Complications associated with severe sepsis and septic shock include acute respiratory distress syndrome (ARDS), acute kidney injury (AKI), disseminated intravascular coagulation (DIC), critical illness polyneuropathy, critical illness myopathy, and septic encephalopathy. The risk of ARDS (and outcome) may be critically dependent on the fluid resuscitation strategy (see below). Sepsis is the leading cause of AKI in critically ill patients and is associated with a hospital mortality exceeding 50% [44,45]. Contrary to classic teaching, animal models and human studies have shown that the sepsis-induced AKI occurs in the setting of preserved or increased renal blood flow [46]. A “unifying theory” has been proposed to explain the development of sepsis-induced AKI, which includes the interplay between inflammation and oxidative stress, microvascular dysfunction, and the adaptive response of the tubular epithelial cell to the septic insult [46]. In addition, a high central venous pressure (CVP) caused by overzealous fluid resuscitation can be transmitted retrograde increasing venous pressures. The kidney is particularly affected by increased venous pressure, which leads to increased renal subcapsular pressure and lowered renal blood flow and glomerular filtration rate [47]. Legrand and colleagues demonstrated a linear relationship between increasing CVP and AKI, with a high CVP being the only hemodynamic variable independently associated with AKI [48]. A CVP >8 mm Hg (as proposed by Early Goal Directed Therapy-EGDT and the Surviving Sepsis Campaign) [49,50] can increase the risk of developing AKI [48,51].

Coagulopathy is a common feature of acute sepsis and comprises a wide spectrum of hemostatic changes ranging from thrombocytopenia and/or subclinical activation of blood coagulation to uncontrolled, systemic clotting activation with massive thrombin formation and fibrin deposition in the microcirculation, eventually leading to consumption of platelets and proteins of the hemostatic system (acute DIC) [26]. The widespread microvascular thrombosis is believed to play a major role in the pathogenesis of the multiorgan dysfunction syndrome (MODS) that is characteristic of severe sepsis and septic shock [52]. The key event underlying the development of DIC is the overwhelming inflammatory host response to the pathogen leading to the overexpression of inflammatory mediators. The latter, along with the microorganism and its derivatives, drive the major changes responsible for massive thrombin formation and fibrin deposition mediated by aberrant expression of
tissue factor mainly by monocytes-macrophages. In addition, impairment of anticoagulant pathways, orchestrated by dysfunctional endothelial cells and suppression of fibrinolysis due to the overproduction of plasminogen activator inhibitor-1 by endothelial cells and thrombin-mediated activation of thrombin-activatable fibrinolysis inhibitor compounds the thrombotic dysfunction [26].
Sepsis is a systemic disease with a variety of clinical manifestations. The initial symptoms of sepsis are nonspecific and include malaise, tachycardia, tachypnea, fever, and sometimes hypothermia. Although most patients with sepsis have an elevated white blood cell count, some patients present with low white blood cell counts, which in general is a poor prognostic sign. A band count in excess of 5% has been reported to have a high specificity (92%) but low sensitivity for the diagnosis of sepsis (43%) [53]. Other clinical manifestations include altered mental status, hypotension, respiratory alkalosis, metabolic acidosis, hypoxemia with acute lung injury, thrombocytopenia, consumptive coagulopathy, proteinuria, acute tubular necrosis, intra-hepatic cholestasis, elevated transaminases, hyperglycemia, and hypoglycemia. Patients may present with clinical features of a localized site of infection, such as cough, tachypnea, or sputum production resulting from pneumonia; flank pain and dysuria with urinary tract infection, or abdominal pain with intra-abdominal infection.

The manifestations of sepsis can sometimes be quite subtle, particularly in the very young, the elderly, and those patients with chronic debilitating or immunosuppressing conditions. These patients may present with normothermia or hypothermia. The failure to generate a temperature greater than 99.6°F (37.5°C) in the first 24 hours of clinical illness has been associated with an increased mortality rate. An altered mental state or an otherwise unexplained respiratory alkalosis may be the presenting feature of sepsis. The signs and symptoms of systemic inflammation are not useful in distinguishing infectious from noninfectious causes of SIRS.

Blood cultures are considered to provide a clinical gold standard for the diagnosis of bacterial infections. However, blood cultures are only positive in between 20% and 30% of patients with sepsis; moreover, it takes 2 to 3 days before the results become available. Despite exhaustive microbiologic tests, a pathogen is not isolated in between 25% and 50% of patients [54]. The use of antibiotics prior to microbiologic testing contributes to the low diagnostic yield of these tests. Molecular diagnostic techniques that do not depend on the growth of organisms in culture may offer distinct advantages over current microbiologic methods. Most of the early molecular methods relied upon culture amplification, which did not resolve the issue of the significant proportion of false-negative cultures. Furthermore, these techniques used targeted pathogen detection with
limited pathogen coverage. SeptiFast (Roche Diagnostics, Germany) was the first real-time polymerase chain reaction (PCR)–based system approved for clinical use. A meta-analysis from 41 phase III diagnostic accuracy studies reported a sensitivity and specificity for SeptiFast compared with blood culture of 0.68 and 0.86, respectively [55]. Similarly, Chang and colleagues performed a meta-analysis evaluating multiplex PCR for the detection of pathogens in patients with presumed sepsis [56]. This meta-analysis, which included 34 studies and 6,012 patients, reported an overall sensitivity and specificity of 0.75 and 0.92, respectively. More recently, advanced PCR followed by electrospray ionization mass spectrometry (PCR/ESI-MS) has been described which can detect more than 800 relevant pathogens in a single assay and which can be completed in approximately 6 hours [57]. The Rapid Diagnosis of Infection in the Critically ill (RADICAL) study was a prospective observational multicenter study that evaluated 529 patients with suspected infection using the PCR/ESI-MS technology [58]. PCR/ESI-MS detected a pathogen in 35% of blood samples compared with 11% for conventional blood culture. This technique holds great promise for the early detection of blood stream infection, allowing for early targeted antibiotic therapy. The major limitation of this technology is that it cannot provide detailed antimicrobial susceptibility data and as such complements standard culture techniques. It is therefore important to emphasize that appropriate samples for culture be obtained prior to initiation of antibiotics to increase the diagnostic yield of these tests. Venipuncture is the preferred method for blood culture collection. Arterial blood samples do not increase diagnostic yield, and blood specimens obtained from intravascular lines have been associated with higher rates of contamination [59]. The Clinical and Laboratory Standards Institute (CLSI) recommends that if one must collect a blood culture from an intravenous line, it should be paired with a culture that is obtained via venipuncture to assist in the interpretation of positive results [60]. The total volume of blood cultured from adult patients is directly proportional to the yield of microorganisms recovered [59,61]. The timing of blood culture collection does not appear to significantly affect the recovery of clinically relevant microorganisms, and most authorities therefore recommend collecting multiple sets simultaneously or over a short period of time [59–61]. Classic teaching suggests that sets of blood cultures be separated in time (20 minutes to an hour); there is, however, no evidence to support this approach, which is logistically problematic and can delay the initiation of antibiotic therapy [61]. Optimally, two to three sets of blood specimens should be collected from independent venipuncture sites, and each set should consist of at least 20 mL of blood [59]. Therefore, the best strategy when performing blood culture is to obtain blood for 4 to 6 bottles (for a total volume of 40 to 60
mL), preferably at the same time [62]. Such a strategy increases the likelihood of obtaining positive blood cultures results yet minimizes the risk of contaminants and reduces the delay in the administration of antibiotics.

A number of biomarkers have been evaluated as adjunctive methods to improve the diagnosis of sepsis. Procalcitonin (PCT) has to date been the most useful biomarker to aid in the diagnosis of sepsis. PCT, a propeptide of calcitonin, is normally produced in the C-cells of the thyroid. In healthy individuals, PCT levels are very low (<0.01 ng per mL). In patients with sepsis, however, PCT levels increase dramatically, sometimes to more than several hundred nanograms per milliliter. The use of PCT for the diagnosis of sepsis and in determining the duration of antibiotics is controversial. The test is not perfect and should always be interpreted in the clinical context together with other diagnostic tests. Wacker et al. [63] performed a meta-analysis to evaluate the diagnostic accuracy of PCT. In this meta-analysis, the sensitivity was 0.77 (95% CI 0.72 to 0.81), the specificity was 0.79 (95% CI 0.74 to 0.84), and the area under the ROC curve was 0.85 (95% CI 0.81 to 0.88). This diagnostic accuracy is better than any other single test to diagnose sepsis. A PCT >0.5 ng per mL is highly suggestive of a bacterial infection, whereas a level <0.1 ng per mL makes this diagnosis less likely [64]. However, the optimal diagnostic threshold is unclear and has been reported to vary from 0.25 to 1.4 ng per mL [64,65]. This variation of diagnostic threshold may partly be explained by the case-mix of each study and the fact that patients with gram-negative infection have significantly higher PCT levels than those with gram-positive infections [66–68]. Infection with a gram-negative pathogen is highly likely in a patient with a PCT level >5 ng per mL. It should be noted that patients with fungal infections usually have much lower or “normal” PCT levels [66]. In hematologic patients, an elevated PCT level within 24 hours after the onset of neutropenic fever is highly predictive of gram-negative bacteremia [69]. In addition to being a very useful test to diagnose bacterial sepsis, the trend in the PCT level is useful for deciding when to discontinue antibiotics [70,71]. Furthermore, the trend in the PCT is strongly predictive of outcomes, with a persistently high level being associated with a poor outcome [72].

Presepsin is a “newer” biomarker that appears to have a diagnostic accuracy that is similar to PCT [73]. Presepsin, also named soluble cluster-differentiation 14 subtype (sCD14-ST), is a 13 kDa protein that is a truncated N-terminal fragment of CD14 [73]. CD14 is a high-affinity receptor for complexes of lipopolysaccharide (LPS) and LPS-binding
proteins (LPB). Presepsin increases significantly in the blood of septic patients, and it has been studied as a marker to differentiate sepsis from other noninfectious causes of SIRS [74–76]. Similarly, soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) levels have been demonstrated to have moderate diagnostic performance in differentiating sepsis from SIRS [77]. The “classic” proinflammatory mediators (IL1, IL-6, and TNF-α) are unable to distinguish between infectious and noninfectious causes of SIRS. IL-27 is produced by antigen-presenting cells on exposure to microbial derived molecules and inflammatory stimuli and has been shown to have a modest ability to predict bacterial infections, especially bloodstream infections [78,79]. It is likely that a decision tree using a number of biomarkers may improve the diagnostic accuracy as compared with a single biomarker alone [79].

Owing to the lack of specific criteria to diagnose sepsis, this diagnosis is often delayed. The early detection and treatment of sepsis are the most important factors for improving the outcome from this condition. However, for many patients admitted to hospital, there is frequently a long delay before the diagnosis of sepsis. Furthermore, it is not uncommon for febrile patients to be sent home from the Emergency Department or the physician’s office with the diagnosis of “flu” only to return hours or days later in overt septic shock. The diagnosis of sepsis therefore requires a high index of suspicion, a comprehensive clinical evaluation together with supportive laboratory tests including appropriate microbiologic cultures, a complete blood count with differential, lactate and when rapidly available PCT levels [80]. It is important to emphasize that unlike PCT, lactate is not a specific “sepsis test.” An elevated lactate is a useful marker of disease severity in patients with sepsis, and sepsis should be considered in the differential diagnosis of patients with an elevated lactate level.

Any one of the following features alone or in combination is suggestive of bacterial sepsis [80]:

Fever >38.3°C or hypothermia (<36°C)
Heart rate >120 per minute (sinus tachycardia)
Systolic BP <90 mm Hg
PCT >0.5 ng per mL
Bandemia >5%
Lymphocytopenia <0.5 × 10³ μL
Thrombocytopenia <150 × 10³ μL
Lactate >2.0 meq per L
Increased neutrophil/lymphocyte ratio (>10:1)
MANAGEMENT OF SEPSIS

The optimal management of patients with severe sepsis and septic shock is highly controversial. It is important to emphasize that there is no Level 1 evidence (data from two or more adequately powered randomized controlled trials (RCTs) or a meta-analysis of RCTs) that demonstrates that any intervention reduces the mortality of patients with severe sepsis or septic shock. Multiple large RCTs have attempted to modulate the immune response or coagulation cascade in patients with severe sepsis and septic shock; these studies have universally met with failure. Although the timely administration of appropriate antibiotics and adequate source control are considered the cornerstones of the management of patients with severe sepsis and septic shock, no RCTs have been performed (or are likely to be performed) that demonstrate the benefit of these interventions. Furthermore, the narrow time window for the administration of antibiotics as advocated by the Surviving Sepsis Campaign Guidelines (administration within 3 hours of Emergency Department triage and within 1 hour of severe sepsis/septic shock recognition) is not supported by a meta-analysis of cohort studies that investigated this issue [81]. This section will focus on appropriate antibiotic therapy, hemodynamic management, source control, and adjunctive therapies that may be of potential benefit in patients with severe sepsis and septic shock.

Antimicrobial Therapy

Empiric intravenous antibiotic therapy should be started as soon as possible after appropriate cultures have been obtained. Although the tight window as suggested by the Surviving Sepsis Campaign is not supported by scientific evidence, common sense would dictate that delaying the administration of antibiotics serves no useful purpose. The choice of antibiotics is largely determined by the source or focus of infection, the patient’s immunologic status, whether the patient has risk factors for a drug-resistant pathogen (DRP) as well as knowledge of the local microbiology and sensitivity patterns. Initial empiric anti-infective therapy should include one or more drugs that have activity against the likely pathogens and that penetrate into the presumed source of sepsis site. Because the identity of the infecting pathogen(s) and its sensitivity pattern(s) are unknown at the time of initiation of antibiotics, for patients with severe sepsis and septic shock the initial regimen should include two or more antibiotics or an extended spectrum β-lactam antibiotic. A number of studies have demonstrated that appropriate initial
antimicrobial therapy, defined as the use of at least one antibiotic active in vitro against the causative bacteria, is associated with a lower mortality when compared with patients receiving initial inappropriate therapy [82,83]. Once a pathogen is isolated, monotherapy is adequate for most infections; this strategy of initiating broad-spectrum cover with two or more antibiotics and then narrowing the spectrum to a single agent when a pathogen is identified is known as “antimicrobial de-escalation” [84]. Antimicrobial de-escalation has been demonstrated to be associated with lower rates of hospital mortality [85]. The indications for continuation of double-antimicrobial therapy include enterococcal infections and severe intra-abdominal infections. In order to rapidly achieve adequate blood and tissue concentrations, antibiotics should be given intravenously, at least initially.

Inappropriate initial antibiotic therapy is usually associated with infection with a DRP. The following factors have been shown to increase the risk of infection with a DRP, with this risk increasing with the number of risk factors: hospitalization >2 days in the previous 90 days, antibiotics during the previous 90 days, nonambulatory status, patients receiving tube feeds, immunocompromised status, acid suppressive therapy, chronic hemodialysis in the preceding 30 days, infection or colonization with methicillin-resistant Staphylococcus Aureus (MRSA) in the previous 90 days, and current hospitalization >2 days [86]. With the widespread use of antibiotics, a group of pathogens have emerged that are resistant to multiple antibiotics. These pathogens, referred to as the “ESKAPE bugs,” have emerged in hospitals in both the developing and the developed world and are the most important DRPs encountered in clinical practice [87,88]. The ESKAPE pathogens include Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumonia, Acinetobacter baumannii, Pseudomonas aeruginosa, and Enterobacter species. Antimicrobial classes for which resistance has become a major problem for the ESKAPE pathogens include β-lactams, the glycopeptides (vancomycin), and fluoroquinolones [89].

The appropriate length of antibiotic treatment for patients with sepsis has not been well established, with marked variation between and within different countries and healthcare settings, independent of factors such as disease severity [90]. Christ-Crain and colleagues randomized 302 patients with community-acquired pneumonia to usual care or antibiotic therapy guided by PCT [91]. In the PCT group, antibiotics were discontinued when the PCT fell to less than 0.25 μg per mL or if the PCT fell by more than 10% in patients with high PCT values on admission.
(PCT > 10 μg per mL). The median duration of antibiotics use was 5 days in the PCT group as compared with 12 days in the usual care group (p < 0.001). There were no differences of outcomes between the two groups. A meta-analysis by the Cochrane group compared a short 7- to 8-day course of antibiotics with a prolonged 10- to 15-day course in patients with ventilator-associated pneumonia (VAP) [92]. This meta-analysis, which included eight studies, demonstrated a reduced recurrence of VAP caused by multi-resistant organisms for the short-course group (OR 0.44; 95% CI 0.21 to 0.95) without adversely affecting other outcomes. Sawyer et al. [93] randomized 518 patients with complicated intra-abdominal infection and adequate source control to receive antibiotics until 2 days after resolution of fever, leukocytosis, and ileus with a maximum of 10 days or to receive a fixed course of antibiotics for 4 ± 1 days. In this study, there were no differences for any of the outcomes studied between the two dosing strategies.

These data suggest that a 5- to 8-day course of antibiotics is adequate for most patients with sepsis who received initial appropriate therapy and have had a good clinical response, with no evidence of infection with a DRP. Patients infected with a DRP generally require 10 to 14 days of treatment. The trend in the PCT level may further aid in determining when it is safe to discontinue antibiotics.

Hemodynamic Support

On November 8, 2001, Emanuel Rivers and collaborators published a study entitled “Early Goal Directed Therapy in the treatment of severe sepsis and septic shock,” in which they compared two protocols for the early resuscitation of patients with severe sepsis and septic shock (for 6 hours in the Emergency Department) [49]. Both protocols used the CVP to guide fluid therapy (target CVP > 8 mm Hg). The “treatment arm” (EGDT) required placement of an oximetric central venous catheter with protocolized interventions to maintain the saturation of the central venous oxygen (ScvO₂) >70%. The study, which enrolled 288 patients (25 were excluded after the fact), reported a 28-day mortality of 49.2% in the control group and 33.3% in the EGDT group (p = 0.01, with an absolute reduction of the risk of death of 16%). Within a short time, this small (severely underpowered), unblinded, single-center study came to be considered the standard of care around the world and formed the basis of the 6-hour resuscitation bundle of the 2004, 2008, and 2012 Surviving Sepsis Campaign Bundles [50,94,95]. However, soon after publication of the EGDT study, concerns were raised regarding the validity of the protocol as well as the conduct and reporting of the study [96–101]. The basic premise of EGDT was to optimize tissue oxygen transport to reverse tissue hypoxia with the use of continuous monitoring to prespecified
physiologic targets. This premise is flawed as bioenergetic failure and cellular hypoxia are likely only preterminal events in patients with septic shock [102,103]. Most importantly, none of the elements of the protocol were supported by strong scientific evidence [96–101]; notably, the CVP is a poor reflection of volume status and fluid responsiveness, patients with sepsis usually have a high rather than a low ScvO₂, with a high rather than a low ScvO₂ being predictive of a poor outcome, that transfusing patients with a hemoglobin >7 g per dL is likely to be harmful and that driving up oxygen delivery (DO₂) without regard to cardiac function is potentially harmful.

In 2014, 13 years after the publication of the EGDT study, the ProCESS and ARISE studies were published [104,105], with PROMISE the final of the Trilogy of large multicenter RCTs being published in 2015 [106]. ProCESS, ARISE, and PROMISE demonstrated that EGDT did not improve outcomes for patients with severe sepsis and septic shock. Patients in the EGDT arm of PROMISE had worse organ-failure scores, a longer stay in the ICU with increased use of resources, and increased costs [106]. A meta-analysis of EGDT, which included the ProCESS, ARISE, and PROMISE studies, concluded that “EGDT is not superior to usual care for Emergency Department patients with septic shock but is associated with increased utilization of ICU resources” [107]. ProCESS, ARISE, and PROMISE together with this meta-analysis have now clearly established that we should move beyond EGDT. This does not mean that the approach to the management of sepsis does not matter! Patients with sepsis should be managed by a thoughtful individualized approach based on an understanding of human physiology, the pathophysiologic changes that occur with sepsis, the patients’ comorbidities, and the best clinical evidence.

Fluid Therapy

Beyond the early administration of antibiotics, aggressive “supportive measures” may be harmful, and the “less is more” paradigm appears applicable for the management of patients with severe sepsis. In these highly vulnerable patients, more intensive treatment may promote the chances of unwanted adverse effects and hence iatrogenic injury [108]. Current teaching suggests that aggressive fluid resuscitation is the best initial approach for the cardiovascular instability of sepsis. Consequently, large volumes of fluid (10 to 15 L) are often infused in the early stages of sepsis. There is, however, no human data that large fluid boluses (>30
mL per kg) reliably improves blood pressure, urine output, or end-organ perfusion [109,110]. This approach is likely to lead to “iatrogenic salt water drowning” with severe ARDS, AKI, and death [111].

The only reason to give a patient a fluid bolus is to increase stroke volume (SV). If the fluid bolus does not increase SV, the fluid bolus serves the patient no useful purpose and may be harmful. This concept is referred to as “fluid responsiveness” [112,113]. By definition, a patient is considered to be fluid responsive if his or her SV increases by ≥10% following a fluid challenge (usually 500 mL crystalloid). The chest radiograph, CVP, central venous oxygen saturation (ScvO₂), and ultrasonography, including the vena-caval collapsibility index, have limited value in guiding fluid management and should not be used for this purpose [114–119]. The passive leg raising maneuver (PLR) or a fluid challenge coupled with real-time SV monitoring are accurate methods for determining fluid responsiveness [112,120,121].

Multiple studies of diverse populations of patients have demonstrated that only about 50% of hemodynamically unstable patients are fluid responsive [112,113]. This implies that for about 50% of hemodynamically unstable patients, fluid boluses may be harmful [111]. This challenges the “well established” notion in critical care medicine, anesthesiology, and emergency medicine that fluid boluses are the “cornerstone of resuscitation.” Owing to increased diastolic compliance and an increase in the unstressed blood volume of septic patients, it is likely that less than 50% of patients with severe sepsis and septic shock are fluid responsive [122]. Large fluid boluses further decrease diastolic compliance of the ventricles, causing the CVP to increase more than the mean circulating filling pressure (MCFP), paradoxically decreasing the gradient for venous return [122,123]. Furthermore, the increased CVP is transmitted backward, increasing venous pressure, which can impair organ function and microcirculatory flow, particularly for encapsulated organs such as the kidney and liver [111]. To make matters worse, the hemodynamic response to fluids in patients with circulatory shock is small and short lived (less than an hour) because most (about 90% to 95%) of the fluid leaks into the tissues [124–127]. Glassford and colleagues performed a systematic review that examined the hemodynamic response of fluid boluses in patients with sepsis [128]. These authors reported that while the mean arterial pressure (MAP) increased by 7.8 ± 3.8 mm Hg immediately following the fluid bolus, the MAP had returned close to baseline at 1 hour with no increase in urine output. Although having a minimal effect on blood pressure, fluid boluses may cause a fall in effective arterial elastance and systemic vascular resistance, potentiating arterial vasodilatation and the hyperdynamic state characteristic of septic shock [129,130]. These data suggest that the majority of patients with severe sepsis and septic shock are not fluid responders. The
hemodynamic changes of the fluid responders are small, short lived, and likely to be clinically insignificant. Furthermore, overaggressive fluid resuscitation will likely have adverse hemodynamic consequences including an increase in cardiac filling pressures, damage to the endothelial glycocalyx, arterial vasodilation, and tissue edema. Consequently, the concept that aggressive fluid resuscitation is the “cornerstone of resuscitation” of patients with severe sepsis and septic shock should be reconsidered [50,94,95,131].

The harmful effects of overaggressive fluid resuscitation on the outcome of sepsis are supported by experimental studies as well as data accumulated from clinical trials [132,133]. Multiple clinical studies have demonstrated an independent association between an increasingly positive fluid balance and increased mortality in patients with sepsis [1,45,134–141]. In a secondary analysis of the Vasopressin in Septic Shock Trial (VASST), Boyd and colleagues demonstrated that a greater positive fluid balance at both 12 hours and 4 days were independent predictors of death [141]. Kelm and colleagues [142] evaluated the fluid status and outcome of 405 patients with severe sepsis and septic shock who were admitted to the Mayo clinic and treated with EGDT. In this study, 67% of patients had clinical evidence of fluid overload at 24 hours with 48% having evidence of fluid overload at 72 hours. Fluid overload was an independent predictor of mortality (odds ratio of 1.92; 95% confidence interval of 1.16 to 3.22). The most compelling data that fluid loading for sepsis is harmful comes from the landmark “Fluid Expansion as Supportive Therapy (FEAST)” study performed in 3,141 sub-Saharan children with severe sepsis [143]. In this randomized study, aggressive fluid loading was associated with a significantly increased risk of death. Nevertheless, despite data suggesting that “aggressive fluid resuscitation” is associated with adverse outcomes and no randomized trials to indicate that this approach improves patient outcomes, the updated Surviving Sepsis Campaign Guidelines, published in April of 2015, mandates the administration of “30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L” within 3 hours of presentation to hospital [114].

In summary, these data support a “conservative” hemodynamically guided fluid resuscitation strategy in patients with severe sepsis and septic shock. From an evolutionary point of view, humans have evolved to deal with hypovolemia and not hypervolemia. Large fluid boluses may counter the live preserving homeostatic mechanisms of unstable critically ill patients, increasing the risk of death [144]. For some patients, hypotension and tachycardia do resolve with limited fluid resuscitation. It is likely that many of these patients have super-added dehydration owing to poor oral intake and a delay in seeking medical attention. However, fluids alone will not reverse the hemodynamic instability of patients with more severe sepsis; for these patients, fluids alone are likely
to exacerbate the vasodilatory shock and increase the capillary leak and tissue edema. On the basis of these data, the initial resuscitation of patients with septic shock should logically include 500 mL boluses of crystalloid (Ringers Lactate) to a maximum of about 20 mL per kg [145]. Ideally, fluid resuscitation should be guided by the determination of fluid responsiveness [112,146]. Norepinephrine should be initiated in those patients who remain hypotensive (MAP < 65 mm Hg) despite this initial limited fluid strategy (see below) [145,147]. The septic patient with an intra-abdominal catastrophe who requires urgent surgical intervention represents one subgroup of patients that may require more aggressive fluid resuscitation. However, overly aggressive fluid resuscitation can result in intra-abdominal hypertension, which is associated with a high risk of complications and death [148,149]. For these patients, continuous SV monitoring is helpful, and ongoing fluid requirements should be guided by the trend in the SV as well as the hemodynamic response to small volume fluid boluses. In addition, perioperative intra-abdominal pressure monitoring is required in these patients [148].

The choice of fluid in patients with severe sepsis and septic shock is controversial. Normal saline (0.9% NaCl) is the most widely used crystalloid around the world. However, normal saline is an unphysiologic solution that is associated with a number of adverse effects. Normal saline causes a hyperchloremic metabolic acidosis [150–153]; it decreases renal blood flow [154] and increases the risk of renal failure [155]. In patients with sepsis, the use of normal saline as compared with physiologic salt solutions has been associated with an increased risk of death [156]. The SPLIT trial was a randomized double-blind, cluster randomized, double-crossover trial conducted in four ICUs in New Zealand that compared 0.9% Saline with Plasma-Lyte 148 for ICU fluid therapy [157]. The risk of AKI (primary outcome) as well as of all secondary outcomes did not differ between the two fluid groups. This study, however, has a number of significant limitations that preclude widespread generalizability of the results; most notably, 71% of patients were postoperative patients, only 4% were diagnosed with sepsis, and the volume of fluid administered was small (about 2.7 L in the first 4 days). Nevertheless, despite the findings of the SPLIT study, 0.9% Saline has no advantages over balanced salt solutions (except in patients with acute necrologic insults) and is best avoided.

Synthetic starch solutions increase the risk of renal failure and death in patients with sepsis and should be avoided [158,159]. The role of albumin
for patients with sepsis is widely debated [160]. Nevertheless, the use of 4% albumin in patients with sepsis was associated with a survival benefit in the SAFE study [161]. In the ALBIOS study, hyperoncotic albumin (20%) was associated with a survival benefit in patients with septic shock [162]. It should be noted that exogenous albumin is one of the few therapies that can restore the endothelial glycocalyx in experimental systems [163]. We recommend the use of hyperoncotic albumin (20% or 25%) in patients with “resuscitated” septic shock who have a serum albumin of less than 3 g per L. Hyperoncotic albumin should not be given as a bolus because this form of administration will paradoxically dehydrate the glycocalyx. If a 20/25% albumin is used to stabilize the glycocalyx, it may be preferable to give this as a continuous infusion at a rate of 10 to 20 mL per hour.

Vasopressors and Inotropic Agents

A low MAP is a reliable predictor for the development of organ dysfunction. When the MAP falls below an organ’s autoregulatory threshold, organ blood flow decreases in an almost linear fashion [164]. Because the autoregulatory ranges of the heart, brain, and kidney are above 60 mm Hg [164], an MAP below this level will likely result in organ ischemia and death [165]. Varpula and colleagues studied the hemodynamic variables associated with mortality of patients with septic shock [166]. These authors calculated the area under the curve (AUC) for various MAP thresholds over a 48-hour time period. The highest AUC values were found for an MAP < 65 mm Hg (AUC 0.83, 95% CI 0.772 to 0.934). Owing to the shift of the autoregulatory range (to the right) in patients with chronic hypertension, a higher MAP may be required in these patients. In the SEPSISPAM study (The Assessment of Two Levels of Arterial Pressure on Survival in Patients with Septic Shock), patients with septic shock were randomized to achieve a target MAP of 65 to 70 or 80 to 85 mm Hg. The primary outcome was 28-day mortality. Secondary outcomes included 90-day mortality and organ failure. A priori a secondary analysis was planned in patients with and without a history of hypertension. Overall, there was no difference in either primary or secondary end-point between the two treatment groups. However, the incidence of organ failure (particularly renal dysfunction) was higher in the subgroup of patients with chronic hypertension in the lower MAP group. Furthermore, much like the Varpula study, the time below the 65 mm Hg (but not 80 mm Hg) threshold was an independent predictor of death. On the basis of these data, we suggest targeting an initial MAP of 65 to 70 mm Hg for patients with septic shock. Among those patients with a history of chronic hypertension, it may be preferable to target a slightly higher MAP (80 to 85 mm Hg) [167].
Norepinephrine is the vasopressor of choice for patients with septic shock \[145,168\]. Dopamine increases the risk of arrhythmias and death and should be avoided \[168–170\]. Similarly, phenylephrine is not recommended as the first-line vasopressor because in experimental models it decreases cardiac output as well as renal and splanchnic blood flow \[171\]. Furthermore, phenylephrine has not been as well studied in patients with sepsis. In patients with septic shock, norepinephrine restores the stressed blood volume, increasing the MCFP, venous return, and cardiac output. Norepinephrine increases arterial vascular tone, further increasing blood pressure and organ blood flow \[145\]. Venous capacitance vessels are much more sensitive to sympathetic stimulation than are arterial resistance vessels, and consequently, low-dose $\alpha_1$ agonists cause greater veno- than vasoconstriction \[172\]. The increase in the stressed blood volume following the use of norepinephrine is caused by the mobilization of blood rather than a short-lived volume expander (crystalloid) \[173\]. Therefore, unlike fluids, the effect of $\alpha_1$ agonists on venous return is enduring and not associated with tissue edema. The early use of norepinephrine in patients with septic shock can increase preload, rendering the fluid-responsive patient fluid unresponsive \[172\]. This may allow the target blood pressure to be achieved and a significant reduction in the amount of fluid administered. Hamzaoui et al. \[174\] have demonstrated that the early administration of norepinephrine increased preload, cardiac output, and MAP, largely reversing the hemodynamic abnormalities of severe vasodilatory shock. Abid and colleagues demonstrated that the early use of norepinephrine in patients with septic shock was a strong predictor of survival \[175\]. It is noteworthy that norepinephrine may be safely given through a well-functioning peripheral venous catheter \[176\], precluding the requirement for emergent central venous catheterization, which is generally regarded as an obstacle to the early use of norepinephrine.

For patients with “refractory septic shock” who remain hypotensive despite an adequate dose of norepinephrine (approximately 0.1 to 0.2 $\mu g$/kg/min), we recommend further hemodynamic assessment to exclude severe systolic ventricular dysfunction, which between 10% and 20% of patients experience. Ventricular function is best assessed by bedside echocardiography and confirmed by minimally invasive cardiac output monitoring. Dobutamine at a starting dose of 2.5 $\mu g$/kg/min is recommended for patients with significant systolic ventricular dysfunction (milrinone is an alternative agent) \[177\]. The dose of dobutamine should be titrated to hemodynamic response as determined by minimally invasive cardiac output monitoring \[177,178\]. For patients with persistent hypotension and hyperdynamic ventricular function (who have severe failure of vasomotor tone), fixed-dose vasopressin (0.03 units per minute) should be initiated. Vasopressin reverses the “relative
vasopressin deficiency” seen among patients with septic shock and increases adrenergic sensitivity [32,179]. Terlipressin is an alternative (although not FDA approved in the United States) [180,181]. The VASST trial randomized patients with septic shock to norepinephrine alone or norepinephrine plus vasopressin at 0.03 units per minute [182]. By intention-to-treat analysis, there was no difference in outcome between the groups. However, an a priori defined subgroup analysis demonstrated that survival among patients receiving $<0.2 \mu g/kg/min$ norepinephrine at the time of randomization was better with the addition of vasopressin than those receiving norepinephrine at a dose $>0.2 \mu g/kg/min$. We therefore suggest the addition of vasopressin at a dose of norepinephrine between 0.1 and 0.2 $\mu g/kg/min$. Thereafter, the dose of norepinephrine should be titrated to achieve an MAP of at least 65 mm Hg.

β-Blockers and Phenylephrine for Septic Shock

As part of the stress response of patients with sepsis and septic shock, there is massive sympathetic activation with very high levels of circulating catecholamines [183]. Septic patients often have an elevated heart rate, even after excluding common causes of tachycardia such as hypovolemia, fever, pain, and agitation. The volume-depleted patient’s tachycardia constitutes the main mechanism that compensates for the decrease in SV. However, persistence of tachycardia after fluid resuscitation (patients who are no longer fluid responsive) may indicate an inappropriate degree of sympathetic activation. Persistent tachycardia has been demonstrated to be a poor prognostic sign in patients with sepsis [184]. In 1987, Parker and colleagues reported that an initial heart rate of $<106$ beats per minute and a heart rate at 24 hours of $<95$ beats per minute were strong predictors of survival [185]. These factors have led investigators to consider the use of β-blockers for the management of “fully resuscitated” septic patients with persistent tachycardia [186,187]. However, reducing heart rate with β-blockers in the early phase of septic shock may potentially lead to an inappropriately low cardiac output with a consequent decrease in organ blood flow, increasing the risk of organ failure.

Morelli et al. [188] randomized 154 patients with “resuscitated septic shock” receiving norepinephrine to maintain an MAP $>65$ mm Hg and who had a persistent heart rate $>95$ beats per minute to an infusion of esmolol (short-acting β1-selective β blocker) or placebo. The esmolol was titrated to achieve a heart rate between 80 and 94 beats per minute.
Twenty-eight-day mortality was 49.4% in the esmolol group versus 80.5% in the control group (HR 0.39; CI 0.26 to 0.59; p < 0.001). For the patients receiving esmolol, there was a significant increase in the Left Ventricular Stroke Work Index (LVSWI) and Stroke Volume Index (SVI). It is important to emphasize that a highly select group of patients were enrolled into this study; these patients may represent only a small fraction of patients presenting with sepsis. The mortality in the control group was higher than that of any study published in the last two decades. Echocardiography was not performed, and it is therefore unclear how many patients had severe isolated diastolic dysfunction. In addition to attenuating the stress response, β-blockers modulate cytokine production, decrease energy expenditure, and modulate protein, fat, and carbohydrate metabolism.

β-blockers should be avoided during the initial resuscitation of patients with severe sepsis/septic shock, patients who are fluid responsive, and patients with predominant systolic LV dysfunction. β-blockers may have a role in the tachycardic septic patient with significant LV diastolic dysfunction. It would appear to be counterintuitive to simultaneously use an infusion of norepinephrine (β1, β2, α1 agonist) and esmolol. In this situation, it would appear more rational to use phenylephrine (α1 agonist) to achieve arterial and venoconstriction together with esmolol (for improvement of diastolic dysfunction). Only a short-acting β-blocker should be used (esmolol), its dose closely titrated and the effects of this combination on cardiac output, blood pressure, and SV closely monitored. β-blockers should be used only for patients who are fluid nonresponsive, for patients undergoing continuous SV monitoring, and after echocardiography has excluded systolic dysfunction.

Resuscitation End Points

A large number of hemodynamic, perfusion, oxygenation, and echocardiographic targets have been proposed as resuscitation goals in patients with severe sepsis and septic shock [50,189,190]. Most of these targets, however, are controversial and not supported by outcomes data. The 2012 and updated 2015 Surviving Sepsis Campaign Guidelines recommend a CVP of 8 to 12 mm Hg (12 to 15 mm Hg if mechanically ventilated), a central venous oxygen saturation (ScvO2) > 70%, and a urine output > 0.5 mL/kg/h as targets for resuscitation [50,114]. As already discussed, targeting a CVP >8 mm Hg may be harmful and, as demonstrated by the ProCESS, ARISE, and PROMISE trials, targeting a ScvO2 >70% does not improve patient outcomes [104–106]. Although urine output may be a valuable marker of renal perfusion in hypovolemic states, this clinical sign becomes problematic for sepsis-associated AKI, where experimental models suggest that oliguria occurs in the presence
of marked global renal hyperemia [191–193]. Titration of fluids to urine output may therefore result in fluid overload. Furthermore, the Surviving Sepsis Campaign guideline recommends “targeting resuscitation to normalize lactate in patients with elevated lactate levels as a marker of tissue hypoperfusion” [50]. This recommendation is based on the notion that an elevated lactate is a consequence of tissue hypoxia and inadequate oxygen delivery [194] and is “supported” by two studies that used “lactate clearance” as the target of resuscitation [195, 196]. However, the concept that sepsis is associated with tissue hypoxia is unproven and possibly incorrect [103, 197, 198]. Increasing oxygen delivery for patients with sepsis is often not associated with increased oxygen consumption [197, 199, 200]. Previous studies have demonstrated that targeting supramaximal oxygen delivery does not improve outcome and may be harmful [201, 202]. Furthermore, in the study by Morelli et al. [188], oxygen delivery was reduced in the esmolol arm as compared with control patients, yet the lactate concentration decreased among esmolol arm subjects, whereas it increased for control arm patients. Although the lactate concentration is an important marker of severity of illness and the trend in lactate may be useful in prognostication, attempts to titrate treatment modalities to a lactate concentration may not be grounded on sound physiologic concepts [197, 198].

The updated Surviving Sepsis Campaign Guidelines [114], which are now mandated by law in the United States (National Quality Forum Measure #0500 [203], Center for Medicare and Medicaid Services SEP-1 Quality measure), require reassessment of volume status and tissue perfusion (after a 30 mL per kg fluid bolus) with either: “repeat focused exam by a licensed independent practitioner including vital signs, cardiopulmonary refill, pulse and skin findings” (all these clinical findings) or two of the following: CVP, ScvO$_2$, bedside cardiovascular ultrasound, or dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge. However, it has been well established that the chest radiograph, CVP, ScvO$_2$, and ultrasonography, including the vena-caval collapsibility index, have very limited value for guiding fluid management and should not be used for this purpose [115–119, 204]. Furthermore, it has been well established that physical examination cannot be used to predict fluid responsiveness and that physical examination is unreliable for estimating intravascular volume status [205].

These data suggest that achieving an MAP of at least 65 mm Hg should be the primary target for the resuscitation of patients with septic shock. Furthermore, while attempts to achieve a supranormal cardiac index may be potentially harmful, we would suggest targeting a normal cardiac index (> 2.5 L/min/m$^2$) [201]. Although a falling arterial lactate concentration is a sign that the patient is responding to therapy
(attenuation of the stress response), titrating therapy to a lactate concentration may not be grounded on sound physiologic principles [197,200]. Additional end points of resuscitation remain unproven at this time.

Source Control

It has been known for centuries that unless the source of the infection is controlled, the patient is often not cured of his/her infective process and that death will eventually ensue. It is important that specific diagnoses of infection that require emergent source control be made in a timely manner (e.g., necrotizing soft-tissue infection, peritonitis, cholangitis, intestinal infarction) and surgical consultation be immediately obtained [50,206]. When source control is required for a severely septic patient, the effective intervention associated with the least physiologic insult should be used (e.g., percutaneous rather than surgical drainage of an abscess) [50,207]. In patients with “urosepsis,” an emergent renal ultrasound or abdominal CT scan should be obtained to exclude urinary tract obstruction, because urgent decompression of the urinary system is required for patients with evidence of obstruction. If intravascular access devices are a possible source of severe sepsis or septic shock, they should be removed promptly after other vascular access has been established [83].

Adjunctive Therapies

A myriad of adjunctive novel pharmacologic agents and interventions have been investigated in patients with severe sepsis and septic shock. To date, none of these therapies have consistently been demonstrated to improve patient outcomes. Ongoing issues that remain controversial include the use of corticosteroids, glycemic control, and nutritional interventions.

Corticosteroids

The use of low-dose corticosteroids in patients with severe sepsis remains controversial [208]. It has been proposed that inadequate cellular glucocorticoid activity (Critical Illness Related Corticosteroid Insufficiency) caused by either adrenal suppression or glucocorticoid tissue resistance results in an exaggerated and protracted proinflammatory response [209]. In addition to downregulating the
proinflammatory response and modulating the anti-inflammatory response, corticosteroids may have additional beneficial effects including increasing adrenergic responsiveness [210] and preserving the endothelial glycocalyx [211]. Although there are divergent recommendations and large geographic variations in the prescription of glucocorticoids, up to 50% of patients with severe sepsis and septic shock receive such therapy [212]. A recent comprehensive meta-analysis that included a trial sequential analysis found no “evidence to support or negate the use of steroids in any dose in sepsis patients” [213]. Consequently, the use of glucocorticoids for patients with sepsis remains unclear. Currently, the Australian and New Zealand Intensive Care Society Clinical Trials Group are performing the ADRENAL study, in which 3,800 patients with septic shock will be randomized to receive hydrocortisone (200 mg per day as a continuous infusion) versus placebo [214]. The outcome of this study will, hopefully, resolve this ongoing therapeutic dilemma.

Nutritional Support

Current Clinical Practice Guidelines (CPG) emphasize early (within 24 to 48 hours of ICU admission) normocaloric enteral nutrition (daily caloric intake estimated to match 80% to 100% of energy expenditure) [215–218] However, a number of recent RCTs have failed to demonstrate an improvement in the outcomes for critically ill patients receiving a normocaloric feeding protocol as opposed to a strategy of intentional hypocaloric feeding. Indeed, a meta-analysis that compared trophic and permissive underfeeding with normocaloric nutrition (included six RCTs) reported no difference in the risk of secondary infections, ventilator-free days, hospital mortality, or ICU length of stay [219].

Early feeding may be particularly harmful for patients with sepsis. Anorexia is an evolutionary preserved acute host response to infection and is likely beneficial to the host. Complex and redundant pathways have evolved to ensure that the host develops anorexia during acute septic insults. Folklore that dates back to the 16th century suggests that “fasting is a great remedy for fever” [220]. The mechanisms whereby decreased nutrient intake is protective and promotes survival during acute illness are not entirely clear. The acute phase response is associated with a dramatic fall in serum iron concentrations [221]. Iron is an essential element required for the survival of many pathogens, and iron deprivation retards bacterial growth [222]. Food restriction results in a dramatic reduction of iron in the liver and serum of a variety of organisms [223]. It has been postulated that fever and iron deprivation act synergistically to inhibit bacterial growth [224]. Starvation promotes autophagy, and this may play a key role in promoting host defenses
Autophagy is a component of innate immunity and is involved in host defense elimination of pathogens [226]. Autophagy contributes to immune response against intracellular bacteria, parasites, and viruses [227]. Autophagy plays a role in the degradation of both extracellular bacterial pathogens that invade the cell (e.g., group A Streptococcus) and true intracellular bacterial pathogens (e.g., \textit{Mycobacterium tuberculosis} and \textit{Shigella flexneri}) [228]. These data suggest that it may be beneficial to withhold enteral nutrition for the first 24 to 48 hours in patients with severe sepsis.

Randomized controlled trials proving that starvation is detrimental to critically ill and injured patients have until recently not been performed. This is likely because of the lack of equipoise by researchers and the notion that such an experiment would be unethical. However, recently, the Dutch Pancreatitits Study Group reported the results of the “Early versus On-Demand Nasoenteric Tube Feeding in Acute Pancreatitits study (PYTHON trial)” [229]; this study comes close to an RCT comparing initial starvation followed by an \textit{ad libitum} diet with early enteral nutrition administered via a feeding tube. In this study, patients with acute severe pancreatitis were randomly assigned to nasoenteric tube feeding within 24 hours after randomization or to an oral diet initiated 72 hours after presentation with tube feeding provided the oral diet was not tolerated. There was no difference in any of the outcome variables between the two groups. Furthermore, there was no difference between the levels of CRP or the SIRS score between the groups over the 1st week, suggesting that early enteral nutrition did not attenuate the inflammatory response.

It should be recognized that in all the RCTs that failed to demonstrate a benefit from early aggressive enteral nutrition, patients received continuous rather than intermittent enteral nutrition [230]. No species eats continuously (day and night), and such an evolutionary design would seem absurd. The alimentary tract and metabolic pathways of humans appear designed for intermittent ingestion of nutrients a few times a day. Humans have evolved as intermittent meal eaters and are not adapted to a continuous inflow of nutrients; normal physiology appears to be altered when this approach is adopted. Continuous as opposed to intermittent enteral feeding likely limits protein synthesis, and this may be an important factor in promoting critical illness–acquired muscle weakness [230]. In addition to adversely affecting protein synthesis, continuous enteral feeding can have other adverse consequences including uncontrolled hyperglycemia, hepatic steatosis, functional changes of the small intestine, and diminished gall bladder contraction [230].

These data suggest that anorexia with limited nutrient intake is an evolutionary preserved response that may be beneficial during the first 24 to 48 hours of acute illness. In those patients who are unable to resume
an oral diet after this time period, enteral nutrition via orogastric tube is recommended. Continuous tube feeding targeting normocaloric goals has not been proven to improve outcome; such a mode of feeding may be unphysiologic.
CONCLUSIONS

Sepsis is a complex and dynamic disease that is difficult to manage by simple treatment algorithms and checklists [231]. Each patient is unique, with a unique set of genes and comorbidities, and responds to illness and its treatment in a unique and often unpredictable manner. This dictates that patients with sepsis be treated with an appropriate physiologic approach that promotes healing and limits the potential for intragenic harm.
REFERENCES

Care of the critically ill has advanced substantially in the past 50 years to the point that patients who previously succumbed to illness or injury may now survive their initial insult. Unfortunately, this places them at risk for multiple organ dysfunction syndrome (MODS), with subsequent failure of organ systems and late mortality [1]. A thorough understanding of the pathophysiology and treatment of MODS is necessary to attempt to mitigate associated secondary morbidity and mortality.

MODS can be defined as “the inability of one or more organs to support its activities spontaneously without intervention” [2]. Initial recognition of MODS came during World War II as advances in resuscitation strategies allowed casualties to survive the initial hemorrhagic shock insult, but rendered them vulnerable to subsequent acute renal failure [3]. Improved intensive care and resuscitation strategies subsequently led to the recognition of pulmonary failure in the form of acute respiratory distress syndrome (ARDS) during the Vietnam conflict [4]. Although advances in support for failing organs, including continuous dialysis and advanced ventilator care, have potentially increased survival, MODS remains a common cause of death in the intensive care unit (ICU).

DIAGNOSTIC CRITERIA AND SCORING SYSTEMS

The severity of MODS determines mortality [5]. Organ failure severity scoring was initially described by Knaus in 1985 [6]. Modern scoring systems consider grade and severity and are intended to serve as predictors of outcome. Among the most commonly used scoring systems are the multiple organ dysfunction syndrome (MODS), sequential organ
failure assessment (SOFA), and logistic organ dysfunction score (LODS) [7–9]. All include clinical and laboratory data for six organs: respiratory, cardiovascular, hematologic, hepatic, renal, and central nervous system (Table 40.1) [10]. The Denver Multiple Organ Failure (MOF) score is a straightforward 4-point scale that has similar or superior specificity to the SOFA score [11]. The Simplified Acute Physiology Score (SAPS) is easy to calculate with available clinical and laboratory data and may in fact be superior to acute physiology and chronic health evaluation (APACHE) in geriatric ICU patients [12]. A “cellular injury score” based on measures of cellular dysfunction has also been described [13]. Specialized scoring systems have been developed for unique populations. For example, the cardiac surgery score (CASUS) outperformed APACHE and SAPS in that special population [14]. No single scoring system has been proven superior, but all predict mortality more accurately than they predict health care resource utilization [11,15].

Denver MOF, Denver multiple organ failure score; SOFA, sequential organ failure assessment; LODS, logistic organ dysfunction score; MODS, multiple organ dysfunction syndrome; PaO₂, blood partial pressure of oxygen; FIO₂, fraction of inspired gas which is oxygen; MV, mechanical ventilation requirement; WBC, elevated white blood count; PAR, pressure-adjusted heart rate; HR, heart rate; CVP, central venous pressure; MAP, mean arterial pressure; SBP, systolic blood pressure; CNS, central nervous system; GCS, Glasgow Coma Scale score; BUN, blood urea nitrogen.

All scoring systems are intended to improve upon clinical judgment. The Denver Emergency Department Trauma Organ Failure Score uses six simple criteria available in the trauma room to predict MODS at 7 days more effectively than unaided emergency department attending judgment [16]. Such predictive models permit resource allocation and can be used to guide patient transfers. The APACHE, originally described by Knaus in 1985 [17], is a scoring system that considers patient factors unrelated to the acute illness as well as acute illness severity. APACHE considers many variables and is therefore not as easily calculable at the bedside as MODS, SOFA, LODS, or Denver, but it reliably predicts both outcome and resource utilization, has been refined to its current version, APACHE IVa, and may be useful for benchmarking ICU performance [18].
Incidence of MODS varies on the basis of primary diagnosis and the scoring system used to determine organ dysfunction. Seventy-one percent of ICU patients have some organ dysfunction [19] and about half have MODS [20], depending on the criteria used. For example, in one adult trauma ICU 47% had MODS, defined by SOFA ≤3 in two or more systems [21]. Septic patients are more likely to have organ dysfunction and more organ failures than nonseptic patients, and mortality is higher in MODS when sepsis is present (31% vs. 21%) [19].
ETIOLOGY

MODS is most often the result of shock, sepsis, and trauma, but there are many causes (Table 40.2) [22]. Forty-one percent of those patients with organ dysfunction have sepsis [19]. Sepsis most commonly originates in the lung (68%) and abdomen (22%), but there are many causes of sepsis-induced MODS [19].

MECHANISMS OF MULTIORGAN DYSFUNCTION SYNDROME

The systemic inflammatory response syndrome (SIRS) is frequently viewed as a predecessor and lies on a continuum of dysfunction with MODS. Components of the SIRS response are seen in virtually all patients following an operation, febrile illness, or injury. SIRS frequently resolves without progression to MODS. MODS may be viewed as a result of an ongoing, dysregulated, or treatment refractory SIRS response with progressive organ system derangement.

Despite extensive efforts, the pathophysiology of MODS is not fully understood and remains an area of intensive investigation [23]. Several mechanisms for the onset and propagation of MODS have been proposed, including an initial insult in which ischemia, oxidative stress, mitochondrial dysfunction, and activation of apoptotic pathways lead immediately to organ failure, and a “two hit” model, where an initial stimulus primes the immune system to respond to a subsequent insult or stimulus with an exuberant reaction, and the concept that dysregulated immune responses lead to MODS [23].

A common theme in the onset and propagation of MODS is the presence of a disordered immune response. It is likely that ongoing tissue hypoxia leads to activation of the acute inflammatory response, oxidative imbalance, structural rearrangement of cellular proteins, dysregulation of the immune system, activation of apoptotic pathways, cell death, and organ dysfunction [24]. Although the inflammatory response is an important component of normal recovery from injury and illness, organ failure appears to result from a loss of the balance between the pro- and anti-inflammatory cascades [25]. The proinflammatory response to a stimulus predominates initially, with increased release of proinflammatory mediators, increased capillary permeability, macrophage and neutrophil activation with tissue invasion and damage, disordered apoptosis, and microvascular thrombosis [26]. This initial response is normally tempered by the anti-inflammatory response, but immune regulation may become dysfunctional. Widespread activation of proinflammatory pathways and impaired balanced resolution by anti-inflammatory pathways can lead to early onset of MODS. If the organism survives the initial insult and onset of MODS, a period of immunosuppression can follow. During this period, the patient becomes susceptible to nosocomial pathogens, with a normally survivable event such as pneumonia representing a life-threatening “second hit” [27].

As research into the pathophysiology of MODS has advanced, another
phase of the process has been recognized. Termed PICS (persistent inflammation, immunosuppression, and catabolism syndrome), this syndrome consists of loss of lean body mass, recurrent sepsis, and increased debility [28]. PICS is associated with functionally irreversible immune system paralysis and may be a significant cause of late death after recovery from the acute phase of MODS [29].
CURRENT MANAGEMENT STRATEGIES

Course of MODS

Outcome for MODS partly depends upon host factors including genetics. Some patients are genetically predisposed to enhanced immune reactivity [30]. For most patients, MODS progression follows a typical sequence first described by Don Fry in 1980 [31], beginning with lung failure, followed by the liver, gastric mucosa, and kidney. Lung dysfunction has since been reaffirmed as the initial manifestation of MODS in the majority of patients [32]. MODS follows a bimodal onset with early and late MODS characterized by different patient characteristics and mechanisms of death [33]. An important distinction must also be made with early organ dysfunction during resuscitation, which is often reversible, and not necessarily the same as early MODS [34].

Respiratory organ dysfunction is the most common early manifestation of MODS but is often not associated with death [35]. Renal, central nervous, and hematologic system impairments characterize MODS progression and are more strongly associated with mortality. Treatment of MODS, therefore, is focused on early recognition of those at risk, removing the proinflammatory pathway trigger, and preventing MODS progression [36]. Clinicians should move briskly to optimize cardiorespiratory function, remove catabolic stressors, and provide nutrition while using antimicrobials selectively and avoiding blood product transfusion. Key advances in the treatment of patients with severe critical illness and MODS that is based on randomized controlled trials are summarized in Table 40.3.

Aggressive enteral nutrition is associated with improved immune function and less mortality in burned children [50]. Landmark study suggested that protein repletion is essential for critically ill patients.

**Resuscitation**

The Surviving Sepsis Guidelines summarize current best practice regarding resuscitation as of 2013 [37]. One major strategy to reduce MODS is to ensure optimal initial resuscitation. Resuscitation should target adequate oxygen delivery and normalization of physiology. Oxygen saturation in mixed venous blood has historically been an important, if not vital, resuscitation target (SvO₂-saturation in mixed venous blood obtained from a pulmonary artery catheter or ScvO₂-saturation in central venous blood obtained from a central venous catheter in superior vena cava). Rivers et al. [38] showed that by using oxygen delivery as a target for resuscitation with fluid, blood, and inotropes, lactic acidemia was less severe and outcomes were improved. Subsequent studies of such “goal-directed therapy” have failed to show similar benefit but those investigations have been conducted in an era when the norm in resuscitation is much more advanced monitoring [39]. There is no question that inadequate initial resuscitation contributes to MODS risk [40]. For a comprehensive discussion of this topic, see Chapter 39.

**Preventing MODS Progression**

Source control is critical to terminate the trigger of the proinflammatory response [36]. Antimicrobials should be used early and be targeted at a broad spectrum of likely organism, then tailored and de-escalated [15]. On the basis of the possible role of the gut and enteric bacteria as a “motor” for MODS, several groups have proposed cleansing the bowel of bacteria to disrupt this relationship, but studies have yielded conflicting results and this practice remains controversial [41]. Although some European studies support parenteral and topical oropharyngeal antibiotics in reducing mortality, this is not widely accepted in the United States [42]. Transfusion is a risk factor for MODS, suggesting that a conservative approach to blood transfusion is appropriate [43].

Mechanical ventilation may contribute to distant organ dysfunction in acute lung injury (ALI) and ARDS [44]. In the ARDSNet trial, the “lung protective strategy” of plateau ≤30 cm H₂O and tidal volumes ≤6 mL per kg body weight was associated with a reduction in all-cause mortality of
9% compared with conventional ventilation with plateau pressures ≤50 cm H₂O and tidal volumes ≤12 mL per kg body weight [45]. A European study affirmed that use of a ventilation strategy with volumes greater than ARDSNet (>7.4 mL tidal volume per kg body weight) increased mortality [46]. For a comprehensive discussion of this topic, see Chapters 163 and 166.

Although Van den Berghe et al. [47] initially reported reduced mortality with intensive insulin therapy and the mortality reduction was in septic MODS, unacceptably high rates of hypoglycemia have since been reported [48] without a mortality benefit.

Steroid therapy in patients with sepsis and MODS may be used for select indications. For a comprehensive discussion of this topic, see Chapter 39.

Nutrition

Early initiation of enteral nutrition is associated with improved outcome for patients with severe trauma, surgery, sepsis, and MODS. MODS may be attenuated among patients receiving enteral nutrition within 24 hours as opposed to initiation later [49,50]. Recent retrospective data support early enteral feeding to reduce ICU and hospital mortality [51]. Both the American and European Societies of Parenteral and Enteral Nutrition (ASPEN and ESPEN) recommend enteral nutrition for ventilated patients when hemodynamics are adequate and gastrointestinal function is sufficient [52,53]. Feeding patients at their full nutritional requirements does not, appear to be necessary early in their ICU course, however [54]. Arginine has been shown to be beneficial for surgical and trauma patients, but cannot be recommended for septic medical patients because of immunoinflammatory characteristics [53]. However, omega fatty acids do appear beneficial for shortening length of stay, ventilator days, and mortality among septic patients in some studies. Serum selenium is depleted in trauma and surgical patients, and some evidence suggests that depletion may contribute to MODS. Selenium repletion reduced MODS in a multi-institutional prospective randomized trial in 2007, but subsequent prospective trials questions its efficacy [55,56]. For a comprehensive discussion of this topic, see Chapters 39, 212, 213, and 214.

Continuous renal replacement therapy has been associated with reduction of MODS severity, theoretically due to alteration of the balance of pro- and anti-inflammatory circulating cytokines [57], but no large
studies currently support its use for this purpose. Renal replacement appears to reduce outcome and length of hospital stay when initiated early but only based upon meta-analyses of smaller heterogeneous studies [58]. Intense interest in renal replacement is reflected in the numerous studies published on the topic to date but well-designed, appropriately powered studies defining the optimal method, risks, and benefits have yet to be performed. Other novel therapies include pharmacologic manipulation of the microcirculation or augmentation of mitochondrial oxidative metabolism to enhance oxygen delivery or utilization [15].
PROGNOSIS AND ICU LENGTH OF STAY

Up to 20% of patients admitted to an ICU develop aspects of MODS, with significantly increased morbidity and mortality [59]. MODS severity is decreasing but ICU mortality remains stable, perhaps because overall acuity is increasing [60]. In an epidemiologic study of sepsis in 2001, Angus et al. [22] determined that dysfunction of one, two, or three organ systems conveys 1%, 4.7%, and 20.7% mortality, respectively. Four-organ dysfunction was associated with 65% to 74% mortality [19,22]. A more recent study examining the outcomes of critically ill patients reported ICU mortality of 10% for failure of three systems or less, increasing to 25% and 50% for four- and five-organ system failure, respectively. Mortality of seven-system failure was 100% [61]. In addition to mortality, MODS can also affect long-term functional outcomes [21].

MODS is the most common reason for prolonged stays in the ICU, exceeding single organ system failure and simply the need for ventilatory support [59]. Determining prognosis for individual patients with MODS remains challenging. Severity of organ dysfunction at the time of ICU admission or during the ICU stay correlates well with mortality, with the highest scores suggestive of a nonsurvivable injury or illness, but does not allow clinically actionable bedside prediction of an individual patient’s outcome [7]. The strongest independent risk factors for death appear to be central nervous system failure (RR = 16.06) and cardiovascular failure (RR = 11.83) [61].
CONCLUSIONS

MODS is largely a result of medical progress and modern ICU care. A common denominator for the pathogenesis of MODS appears to be cellular hypoperfusion, leading to an imbalanced immune response, with resultant organ damage and failure. Treatment of patients at risk for MODS is supportive, ensuring adequate resuscitation, nutritional support, infection or tissue injury source control, and support of individual organ system functions. Despite modern critical care, MODS remains a common cause of death among critically ill patients.
REFERENCES

The CDC estimates that traumatic brain injury (TBI) results in over 2.5 million ER visits, nearly 300,000 hospitalizations, and over 50,000 deaths annually in the US. Up to 3 million people are living in the US with disabilities related to TBI [1]. Falls are the most common of the causes overall, often seen among the pediatric and elderly populations. Motor vehicle accidents follow and are the most common cause among those aged 14 to 35. The estimated annual financial burden is 3 billion dollars for initial hospitalization costs to 60 billion dollars overall [2–4].

TRAUMA BAY AND INITIAL CRITICAL CARE

Care of the TBI patient involves early stabilization and longitudinal care to halt deterioration and maximize recovery. Injury from TBI is commonly divided into two subtypes. Primary injury is dealt directly to the brain by the initial insult and can be modified only by prevention. Much of prehospital, emergency department, and ICU care has long been targeted at reducing secondary injury, which affects up to 91% of TBI patients [5]. Hypotension, hypoxia, hemorrhage, intracranial hypertension, cerebral edema, seizures, and metabolic derangements all contribute to secondary injury [6]. Studies of permissive hypotension, a strategy for hemorrhagic trauma, have excluded patients with TBI owing to the concerns over cerebral perfusion pressure [7]. Systolic blood pressure is maintained over 90 mmHg, and management to maintain adequate cerebral perfusion pressure (CPP) improves outcomes [8,9]. Corticosteroids are contraindicated for the management of brain edema related to TBI because they are associated with worse outcomes [10].

The mainstay of urgent neuroimaging remains computed tomography (CT). Although MRI is more sensitive for axonal injury, small hemorrhage, and ischemia, CT is rapid, readily available, and more

Isotonic fluids remain the primary vehicle for volume resuscitation. Studies of hypertonic saline as resuscitation fluid have been equivocal; 7.5% saline solution and 500m Osm per L sodium lactate showed improved outcome, while a study using 7% saline solution revealed no benefit [11–13]. Hyponatremic or hypoosmotic fluids induce and exacerbate cerebral edema and are avoided during resuscitation and throughout the critical care phase of TBI, even in the presence of hypernatremia. 5% dextrose as a resuscitation fluid for non-brain injured children has been associated with the evolution of cerebral edema [14]. A rat model of TBI comparing ringers lactate and 5% dextrose infusions reported significantly increased mortality for animals treated with 5% dextrose [15].

Mannitol1gm per kg IV is the first choice for measured or when elevated ICP is presumed. Preoperative high-dose mannitol, 1.4gm per kg IV, benefits patients requiring emergent surgery for subdural and temporal lobe hematomas [16,17]. Mannitol is infused through a 5-micron filter and must not be infused through a cooled catheter such as those used for targeted temperature management, owing to the risk of precipitation of mannitol out of solution. Hypertonic saline solutions including 23.4% saline may be used in place of mannitol during trauma resuscitation and may improve outcomes [18]. An advantage favoring hypertonic saline is that it acts as a volume expander, whereas mannitol acts as an osmotic diuretic, possibly reducing the effectiveness of volume resuscitation. However, 23.4% saline solution must be infused through a central venous catheter, and issues surrounding the storage of concentrated electrolytes in Emergency Departments raised by the Joint Commission have prevented 23.4% saline from competing effectively with mannitol for this role in many centers [19].

Seizures may increase intracranial pressure and may lead to secondary injury. Prophylaxis during the first 7 days after severe injury is standard of care, though this has not been shown to alter long-term mortality, or even the incidence of long-term epilepsy. Phenytoin is a common choice as it is available in enteral and IV formulations, and levetiracetam is popular because of its low incidence of interactions. Neither has been shown to be superior to the other [20].

Reversal of Anticoagulation

Reversal of anticoagulation must be performed promptly for TBI patients
with ICH [21]. Among patients receiving vitamin K antagonists with International Normalized ratio (INR) over 1.4, vitamin K 10 mg IV should be given, conventionally followed on days 2 and 3 by 5 to 10 mg enterally [22]. Reversal of anticoagulation with four-factor prothrombin complex concentrate (PCC), dosed by weight, and INR is faster than and superior to plasma transfusion [23–25]. KCentra is a PCC FDA approved for warfarin reversal among patients with major bleeding or requiring urgent surgery. For patients with a history of heparin-induced thrombocytopenia in the past 90 days, plasma transfusion or factor VIIa dosing may be considered because KCentra contains a small amount of heparin.

The anticoagulant effects of the direct thrombin inhibitor dabigatran (Pradaxa) can be reversed by the FDA approved reversal agent idarucizumab, which binds and inactivates dabigatran. If idarucizumab is not available, KCentra, hemodialysis, and hemofiltration have been attempted [26].

Factor Xa inhibitors currently lack a reversal agent, though andexanet alfa is moving through the approval process and is expected to be available. KCentra has been reported as a possible reversal agent [26].

For patients receiving aspirin, platelet transfusions may be considered for patients requiring urgent neurosurgery [27]. Transfusion is not as useful for patients receiving GPIIB/IIIa inhibitors as the transfused platelets are inactivated [26], though salvage transfusion is often considered.

**Surgical Therapies for TBI**

Surgical hematoma evacuation is commonly performed acutely for subdural hematomas over 1 cm in width and epidural hematomas with significant mass effect or progression. Routine evacuation of parenchymal hemorrhages is not indicated, as violation of otherwise healthy or recoverable tissue may be required to access the hematoma. However, intracranial hypertension refractory to medical management may be an indication for resection of parenchymal hematomas [28,29].

Decompressive craniectomy has historically been viewed as a last resort for management of TBI with intracranial hypertension [29,30]. One complication of decompressive craniectomy is injury to the brain tissue and blood vessels, especially veins, at the edges of the craniotomy defect. Authors recommend removal of at least a 12-cm-diameter bone flap, and extension of the craniectomy to the temporal bone is also sometimes recommended [31,32]. A retrospective review of TBI patients treated with decompressive craniectomy found no outcome benefits compared to historical controls. For many patients, surgery was performed late in the ICU course, and the subgroup of patients who had
earlier surgery did have better outcomes at 6 months compared to controls [28]. Analysis of a non-randomized series of patients with GCS ≤9 and a midline shift greater than the width of an extra axial hematoma who were considered for decomplicative surgery revealed that the treated patients had worse GCS on admission, but more survived to discharge and more were discharged to home or skilled nursing than those of the non-surgical group [29]. The often cited DECRA study randomized patients prospectively to decomplicative surgery or medical therapy. This study demonstrated harm in the treatment group, however was plagued by problems with randomization in that the treatment group had significantly more patients with unreactive pupils than the medical group, and the study had intended to exclude patients with unreactive pupils altogether [33].

**Neurological Critical Care**

**Multimodality Monitoring**

Neurological monitoring relevant to TBI is covered in depth in Chapter 31. Although the physical examination remains the gold standard for neurological monitoring, many patients with severe TBI require sedation and other therapies, which make surrogate monitoring mandatory. Although important for the reduction of the duration of mechanical ventilation and the prevention of VAP [34], interruption of sedation is contraindicated for patients with elevated ICP [35]. Elevated ICP, particularly when not responsive to therapy, is associated with worse outcomes [36]. The recent BEST-TRIP trial demonstrated no improvement of outcomes with a protocol driven by ICP over one guided by clinical observations [37,38]. However, ICP monitoring remains the standard of care where available and is supported by consensus statements including one to which BEST-TRIPs lead investigator was a contributor. Although brain edema may preclude the selection of an external ventricular drain (EVD) over a parenchymal ICP monitor, EVDs have the advantage of offering the ability to decrease ICP by draining CSF and are thus favored when feasible, especially when hydrocephalus is present [35]. EEG is indicated when the mental status is worse than anticipated given the known injuries, and continuous EEG is favored [35]. Poor brain tissue oxygen tension is a predictor of poor outcome, and treatment guided by brain tissue oximetry has been shown to improve outcomes [39,40], and even with the use of brain oximetry or metabolic monitoring, ICP monitoring is still required [35]. See Chapter 31 for more detail.
**Treatment of Elevated Intracranial Pressure**

For all patients with elevated intracranial pressure, maintenance of intravascular volume is important because it improves cerebral perfusion pressure. For patients with significant acidosis or those requiring high volumes of crystalloid, the substitution of isonatremic sodium acetate for sodium chloride may limit the development of hyperchloremic metabolic acidosis [41]. Adequate analgesia and anxiolysis can help maintain adequate ICP. Head elevation to 30 degrees above horizontal decreases intracranial pressure without sacrificing cerebral perfusion or oxygenation [42].

**Mannitol**

Mannitol has long been known to lower intracranial pressure [43,44]. Doses of 0.25 to 1.4 g per kg IV are commonly used every 3 to 8 hours [16,45–47]. Our center favors 1gm per kg, rounded to the nearest 25gms, every 6 hours, to allow approximately 5 half-lives between doses and to avoid the development of idiogenic osmoles, which may lead to tolerance of osmotherapy [48,49]. Acutely with rapid infusion, mannitol increases circulating volume, blood pressure, and cardiac output and decreases blood viscosity [50,51]. This may lead to decreased ICP via an increase in CBF and autoregulatory decrease of cerebral blood volume (CBV) [45]. Mannitol also acts as an osmotic diuretic, recruiting water from the interstitial space through the blood brain barrier, which is nearly impervious to mannitol. Mannitol has been shown to preferentially shrink brain tissue where the blood–brain barrier is intact, though it has been shown that midline shift does not increase with mannitol’s use [52,53].

Mannitol may leak into damaged brain tissue, but has been shown to leave that tissue once it clears the bloodstream. Additionally, it does not accumulate in concentrations higher than those of plasma; thus, no reverse gradient exists to exacerbate cerebral edema [49,54,55]. Mannitol clearance from the bloodstream can be monitored by measuring the osmotic gap [56,57].

**Hypertonic Saline**

Hypertonic saline (HS) may be used to decrease intracranial pressure, and like mannitol, HS has hemodynamic effects in addition to its osmotic
effects on cerebral edema [48,58–60]. The use of HS at concentrations varying from 3% infusions to 29.2% boluses has been shown to improve ICP both as a primary measure and when mannitol fails [41,58,61–63]. At our center, we use 15 to 30 mL boluses of 23.4% sodium chloride every 4 to 6 hours when mannitol fails to control ICP or when renal failure precludes the use of mannitol. Randomized trials comparing serial doses of mannitol to hypertonic saline are not conclusive. Loss of efficacy of ICP control when HS is used over several days time may be due to the formation of osmoles, as persistent hypernatremia frequently develops.

The relationship between hypernatremia, renal function, and outcomes is a complex one. Only one study has directly examined the relationship between varying levels of hypernatremia and outcomes [64]. Though patients with more severe injuries were more likely to be hypernatremic, likely owing to more aggressive osmotherapy, there was an independent association between a finding of serum sodium over 160 mEq per L and mortality. Although it is well known that hypernatremia in the setting of hypovolemia is associated with renal failure [65], the safety of euvoletic hypernatremia is not known. It is also known that a rapid decrease of serum sodium may lead to cerebral edema among healthy patients, and the dangers of hypotonic fluid administration for patients and experimental models with cerebral edema have been described above. When significant hypernatremia develops among patients with cerebral edema, it may be safer to limit treatments which raise sodium while resisting treatments which directly lower it. Diabetes insipidus is an ominous sign among those with TBI [66]. Treatment with vasopressin or DDVAP to limit free water diuresis may be a safer way to combat hypernatremia in this setting than parenteral-free water administration.

Cerebral Perfusion Pressure and the Lund Concept

In contrast to purely ICP based management, the “Lund Concept” describes a strategy for lowering ICP based partially on decreasing CPP [67,68]. In this strategy, it is postulated that increases of MAP may exacerbate cerebral edema, especially when large amounts of crystalloid solutions are administered. MAP is lowered to decrease hydrostatic capillary pressure and ameliorate cerebral edema. Mannitol and vasopressors are generally avoided. CPP is tolerated as low as 50 mmHg. Multimodality monitoring, often including bedside microdialysis, is required to monitor the metabolic reaction of vulnerable tissue to decreased CPP.

Temperature Management

Hyperthermia increases the body’s metabolic demand, worsens cognitive
impairment, and has been associated with worse outcomes among multiple models of neurological insults [69]. Induced hypothermia has been shown to improve neurological outcomes after witnessed cardiac arrest [70,71]. Recent studies suggest a target temperature of 36°C is as effective as a target of 33 degrees; however, this has not been studied for TBI [72]. Induced hypothermia has been shown to improve outcomes using animal models [71,73,74]. The first hour after injury was found to be critical. A series of large, multicenter trials, however, failed to show a benefit of prophylactic-induced hypothermia after TBI [75–77].

Still, Class I evidence shows that induced hypothermia lowers ICP [78]. Side effects include hyperglycemia, immunosuppression, hypovolemia, and electrolyte imbalances largely due to “cold diuresis” [71]. Rapid rewarming or overshoot may lead to rebound intracranial hypertension and impaired cerebral vasoreactivity [79]. Patients presenting with mild hypothermia after TBI should not be aggressively rewarmed [71]. Fever, defined as core body temperature over 38°C, affects up to 68% of TBI patients within 72 hours of admission and is associated with worse outcome [69]. Although much effort is spent in ICUs to reduce fever, and induction of hypothermia remains a hot topic in critical care literature, neither effort has been conclusively shown to improve outcomes after TBI.

**Induced Coma**

Pharmacologically induced coma may be an appropriate step taken when ICP and CPP cannot be managed by the above means [80,81]. Prophylactic administration of barbiturates does not improve outcomes [8]. Pentobarbital is the most common agent reported for this purpose and is postulated to lower ICP by reducing the cerebral metabolic rate of oxygen (CMRO$_2$). Pentobarbital has numerous side effects, including hypotension, cardiac depression, immune system suppression, and hypothermia. Close attention must be paid to the maintenance of adequate hemodynamics [81,82]. Coma is induced with a slow bolus 5 to 10 mg per kg of pentobarbital, followed by an infusion of 1 to 3 mg/kg/h. Although many centers check pentobarbital levels, continuous EEG monitoring provides a more useful measure of dose effect, with the goal being a reduction of ICP to acceptable levels and the induction of burst suppression on EEG [80]. Serum drug levels are of value when evaluating for CNS function, for example, when brain death is contemplated and the clearance of drug from the bloodstream must be confirmed. Propofol has also been described as an agent for ICP control. When used to achieve burst suppression, a 2mg per kg loading dose followed by an infusion of up to 200g/kg/h is required. Severe hypotension and propofol infusion syndrome are concerns when using high-dose propofol.
Systemic Critical Care

Mechanical Ventilator Management

Hypoxia and hypercarbia may exacerbate secondary injury and complicate ICP and CPP management [83]. The Brain Trauma Foundation recommends maintaining SpO₂ over 90% and PO₂ over 60 for TBI patients [8]. Advanced modes of mechanical ventilation and inotropic and/or vasopressor are frequently required to maintain CPP and adequate gas exchange. For some patients, hypoxia may be resistant to conventional ventilator settings, and increases in PEEP and FIO₂ may be required.

Concern has been raised over the effect of PEEP on ICP. Published data, however, reveal varying effects of PEEP on ICP. One theory posits that PEEP raises intrathoracic pressure, thus decreasing venous return to the chest and thus increasing the volume of venous blood inside the cranial vault, leading to a rise in ICP [84]. In reality, it is unclear to what extent changes of PEEP are transmitted into the thoracic cavity, much less into the vascular system where venous return could be affected, especially among patients with ARDS where the stiffness of the diseased lung may not transmit PEEP efficiently [85]. A series of TBI patients with ALI/ARDS reported that ICP was more tightly associated with PCO₂ than levels of PEEP [86]. For refractory hypoxia, prone positioning has been reported in several series. Although in some neurocritical care series raised ICP has been reported, in a dedicated series on TBI patients with ARDS prone positioning was associated with improved oxygenation without detrimental effects on ICP or CPP [87,88].

Ventilation of the TBI patient demands attention to systemic acid base balance and to secondary effects on cerebral blood flow. Therapeutic hyperventilation (HV) is the fastest way to lower ICP, causing rapid vasoconstriction of the cerebral arterial supply. Animal experiments and human observations reveal that HV causes a decrease in the partial pressure of oxygen in brain tissue (PbtO₂) [89,90], is now contraindicated during the acute phase of TBI, and is discouraged by most authorities [8,89]. Even for normal brain tissue, decreases of PCO₂ below 30mmHg resulted in decreased CBF and evidence of anaerobic metabolism [89]. Although evidence of harm with less aggressive HV is lacking, evidence for its benefit is absent. This intervention cannot be
recommended with enthusiasm. If used when other measures fail, HV should be monitored with one of the markers for tissue stress, such as brain tissue oximetry or microdialysis [91].

**Glucose Management**

A 2001 multicenter trial revealed that tight glycemic control improves outcome in critical care populations [92]. This finding leads to a revolution of ICU glucose management, with many hospitals implementing ICU-based protocols targeting maximum serum glucose levels from 110 to 140 mg per dL. More recent trials have questioned this result, prominently the NICE SUGAR trial, which revealed increased mortality of patients treated with a tight control protocol targeting serum glucose under 108 mg per dL compared to a protocol targeting glucose under 180 mg per dL [93]. For the TBI and neurocritical care population, concerns have been raised over glucose delivery to regions of vulnerable brain tissue, which may already be at risk of poor perfusion owing to cerebral edema. A study using microdialysis to examine glucose delivery revealed significantly low brain glucose levels associated with signs of metabolic stress among patients treated with a tight glycemic control strategy [94]. A meta-analysis concluded while blood sugars over 200 mg per dL were likely harmful, overly tight glycemic control was also harmful and a blood sugar target of under 180mg per dL was suggested [95].

**Nutrition and Metabolism**

A thorough review of the literature regarding energy expenditure of TBI patients found that historically held beliefs regarding brain injured patients’ elevated metabolic rates and nutritional needs are valid [96]. Moderate to severely injured TBI patients exhibited metabolic rates 96% to 132% of predicted baseline when sedated and 105% to 160% over base when awake. Another review documented some findings where hypermetabolism reached 200% of predicted baseline [97]. TBI patients are also catabolic, exhibiting a −3 to −16gm per day nitrogen balance. The resultant decrease of muscle mass and related immune function deficits may worsen outcomes [96]. Although the common practice is to prescribe nutrition targeted to exceed baseline predicted needs by 40%, these authors favored the use of indirect calorimetry to better target each patient’s individual needs. Although upper GI intolerance is common early among those with TBI, placing patients at risk for aspiration pneumonia, some studies do show a trend to improved outcomes with the institution of early feeding [96]. No conclusive data exist to suggest favoring post-pyloric feeding to gastric feeding.
Prevention of Venous Thromboembolism

Pulmonary embolism is the 3rd leading cause of death among patients surviving past day one of TBI [98]. Trials comparing early to late chemoprophylaxis are lacking. Low molecular weight heparin (LMWH) is superior to unfractionated heparin (UFH) for preventing venous thromboembolism among patients with polytrauma and spinal cord injury, but data regarding TBI patients are limited. Consensus guidelines support therapy with intermittent pneumatic compression systems within 24 hours of admission and chemoprophylaxis with LMWH or UFH starting 24 to 48 hours after admission or completion of surgery as long as there is no evidence of continued bleeding [99].

Specialty Injury Subtypes

Penetrating Brain Injury

High-energy missile trauma produces brain injury through multiple mechanisms. Brain tissue along the tract of the missile is injured directly. With high-energy projectiles, a wave of energy precedes the missile, and significant damage is delivered by a wave of cavitation, which follows in the wake of the projectile. This cavitation may reverberate through the cranium, reflecting off the inside surface of the dura and skull [100,101]. Contusions, intracranial hemorrhage, and subdural and epidural hemorrhage may result. Vascular injury is common when the path of injury crosses near vascular structures, and arterio-venous fistulas and pseudoaneurysms may develop [101]. Vasospasm may develop early or late in the ICU course. Critical care focuses on control of intracranial pressure using methods similar to those used for closed head injury. Surgical debridement is indicated for missile and bone fragments in non-eloquent areas of the brain only [102]. Historically, from 15% to 50% of wounds become infected and antibiotic prophylaxis is standard practice. There is no consensus on which antimicrobials are more appropriate; most surgeons favor cephalosporins, whereas some centers use combinations including cephalosporins, metronidazole, and vancomycin. Invasion of an open-air sinus by the injury raises the risk of infection and may warrant broader coverage [101].

Blast Related Trauma

Experience in Iraq, Afghanistan, and to an extent Lebanon has revealed a previously poorly recognized variant of TBI: that delivered by blast injury [103–105]. With current protective armor, many warfighters survive
previously fatal battlefield injuries \cite{104,106}. Combatants and civilians exposed to high-energy blast trauma suffer brain injuries, which may have features seen in both closed and penetrating TBI \cite{104}. Pseudoaneurysms and vasospasm were commonly detected among a cohort of \cite{103} patients imaged either because of injury known to be near or involving cerebral vasculature or because of unexplained deterioration of neurological function. The prevalence of vasospasm and pseudoaneurysm in the general blast TBI population was not investigated. Vasospasm was been recognized as early as 48 hours after blast TBI and may occur as late as 10 to 14 days after injury. Warfighters returning to rehabilitation hospitals with severe injuries did demonstrate recoverability even in the worst cases; up to 50\% of patients presenting to stateside rehabilitation with GCS score 3 to 5 eventually recovered to a Glasgow Outcome Scale (GOS) score $\geq 3$ at 1- to 2-year follow-up \cite{107}.

### Associated Vascular Injuries

Both blunt and penetrating trauma to the head and neck may induce the formation of aneurysms. Intervention is indicated when aneurysms are accessible to surgical or endovascular repair \cite{108,109}. Dissections of the carotid and vertebral arteries may occur among TBI patients, especially when trauma also includes the cervical spine. Dissections may lead to ischemic strokes by either leading to occlusion of the involved vessel or by serving as an embolic source \cite{108,110}. Treatment for dissections includes avoidance of hypertension and mitigation of embolic risk. Both antiplatelet drugs and heparin have significant hemorrhagic risks for patients with concomitant brain injury \cite{111}. In extreme cases, surgical or endovascular occlusion of the affected vessel may be the safest choice to limit embolic risk \cite{108,112}.

### Long-Term Outcomes

Prediction of outcomes after TBI is difficult due to the heterogeneity of the different injury subtypes, varying levels of concomitant non-neurological injuries, and medical complications of critical care. Bedside physician estimates of prognosis are often either overly pessimistic or unrealistically optimistic. When studied, physicians have reported that they feel their predictions are often inaccurate \cite{113}. The need for better prognostication tools, as well as aids for shared decision making, has been noted by the CDC as recently as 2015 and is the subject of ongoing research \cite{114,115}. Treatment by a specialized neurocritical care team is
associated with decreased hospital costs, decreased length of stay, and improved outcomes at 6 months [116,117].

Findings of bilaterally fixed pupils confer a 70% to 90% likelihood of death or persistent vegetative state as the final outcome [11]. Absent bilateral Somatosensory Evoked Potentials (SEP) early in the ICU course predict death, whereas initially normal bilateral readings predict good outcome. SEPs may fluctuate over the course of each day; thus, single recordings are less informative than serial examinations, and improvement within the first 10 days predicts recovery [118,119]. Serial physical examinations combined with aggressive resuscitation for 72 hours are recommended by consensus guidelines [120,121].
REFERENCES

INTRODUCTION

The incidence of traumatic spinal cord injury (SCI) is approximately 40 SCIs per million persons per year in the United States [1]. Most traumatic spinal cord trauma (80.6%) occurs in males and most cases are among Whites (66%), followed by African Americans (26.2%) and Hispanics (8.3%). There has been an increase in the average age of injury since the 1970s from 28.7 years to 41 years. This is owing to an increase in people older than 65 years in the general population and a decrease in childhood trauma [1]. Traumatic SCI in the United States is reported to occur by motor vehicle accidents (47%), falls (23%), personal violence (14%), sports injuries (9%), and other sources of trauma (7%) [1].

Cervical injuries (C1–C7) account for approximately 55% of all traumatic SCIs. In the thoracolumbar spine, the most common location of fractures is between T12 and L2, with SCI in 10% to 25% of these fractures [2]. Thoracic fracture patients with less severe neurologic deficits have more favorable prognosis in the recovery of overall general health status compared to those with more significant neurologic deficits [3].

The trauma surgeon works as a part of a multidisciplinary team. A high degree of suspicion for spinal column injury with neurologic impairment must be maintained upon evaluation of most trauma patients. As the trauma team leader, he or she must be able to appropriately identify the pertinent history, examine the patient, provisionally stabilize the patient and the spine, and order appropriate imaging to identify or rule out injuries that may require orthopedic or neurosurgical consultation.

In order to execute these key fundamentals, a surgeon must understand the relevant anatomy, injury mechanisms, injury patterns, pathophysiology, and associated physical findings. Familiarity with “first responder” and in-hospital provisional spinal stabilization methods,
patient resuscitation measures, and monitoring is the key to proper treatment.
ANATOMY

Spinal Column

The normal spinal column consists of 33 vertebrae, including 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal vertebrae. When anatomy is normal, the cervical and lumbar spines are lordotic, and the thoracic and sacral spines are kyphotic. These curvatures help to balance the spine and evenly distribute forces.

C1, which is also called the atlas, has neither a vertebral body nor a spinous process (Fig. 42.1). It is a ring-like structure with anterior and posterior arches separated by lateral masses on each side. It has two superior concave facets that articulate with the occipital condyles, accounting for approximately 50% of the neck flexion and extension [4].

FIGURE 42.1 Anatomy of C1 (Atlas) and C2 (Axis) [40].
C2, which is also called the axis, has an odontoid process (dens) and vertebral body (Fig. 42.1). It articulates with C1 (atlanto-axial) and accounts for 50% of cervical rotation. There is a vascular watershed area between the apex and base of the C2, and this limited blood supply is thought to affect healing in Type II odontoid fractures. The dens articulates with the posterior aspect of the anterior ring of C1 and is stabilized by the transverse ligament. There is no intervertebral disc at either the atlanto-occipital or the C1–C2 joints.

C1–C7 vertebrae typically have a transverse foramen, and the vertebral artery travels through the transverse foramen of C1–C6 in the majority of individuals. C7 has a prominent spinous process and is a useful landmark during physical examination.

In the thoracic spine, the articulations with the ribs lead to increased rigidity. Therefore, more force is required to produce a fracture in the thoracic region than the cervical or lumbar region.

The cervicothoracic junction represents a region that transitions from the fairly mobile cervical spine to the fairly rigid thoracic spine. Furthermore, it represents a transition from the lordotic cervical spine to the kyphotic thoracic spine. Biomechanically, this construct creates significant stress on the cervicothoracic junction. Disruptions of this anatomical region by trauma or tumor can lead to significant instability. Similarly, at the thoracolumbar junction, the vertebral column transitions from a relatively stiff construct in the thoracic spine to a more flexible construct. This transition point, especially T11–L2, acts as a zone of stress concentration and is more susceptible to injury than other adjacent portions of the spine.

**Spinal Cord**

The spinal cord is a tubular nervous tissue that extends from the brainstem and typically terminates as the conus medullaris at the inferior border of L1. Extending from the distal tip of the conus medullaris, the cauda equina consists of the lumbar and sacral nerve roots and filum terminale surrounded by dura. The spinal cord acts as a shuttle that relays neuronal signals from the brain to the rest of the body and vice versa. Specific neural fibers with similar function form “tracts.” Ascending tracts relay sensory information from the body to the brain and the descending tracts relay motor function to the body.

Ascending tracts include the dorsal columns, lateral spinothalamic tract, and ventral spinothalamic tract. The dorsal columns convey deep
touch, proprioception, and vibratory sensation. The lateral spinothalamic tract conveys pain and temperature and the ventral spinothalamic tract conveys light touch. Descending tracts are comprised of lateral and ventral corticospinal tracts, which carry voluntary motor signals to the body.

The blood supply to the spinal cord originates from the segmental vessels, which are branches of the great vessels at the neck, thorax, and abdomen. These segmental vessels divide into anterior and posterior radicular arteries, which transverse the neuroforamen along with the segmental nerve root. The anterior and posterior radicular arteries finally terminate as the anterior and posterior spinal artery. The anterior spinal artery is the primary blood supply of the anterior two-thirds of the spinal cord, which includes the lateral and ventral corticospinal tracts. The posterior spinal artery is the primary blood supply to the dorsal sensory columns [5].
The vertebral column serves to transmit loads, permit motion, and protect the spinal cord. Spinal stability is one of the most important considerations in the management of spinal trauma. White and Panjabi defined spinal stability as the “ability of the spine under physiologic loads to limit patterns of displacement so as not to damage or irritate the spinal cord or nerve roots and, in addition, to prevent incapacitating deformity or pain due to structural changes.”

An ideal spinal column injury classification should be both descriptive and prognostic. The system should have consistent radiographic measures and guide clinical decision-making. There are a number of historical spinal trauma classification schemes utilized to assess the stability of the spine. The majority of them are not validated and based on retrospective views and experiences of individual surgeons. These systems are typically based on either mechanistic or anatomic description of spinal column injuries. Although there are numerous proposed injury classifications, many of them are not prognostic and do not guide clinical decision-making.

The Denis classification is an example of a three-column theory based on anatomic description of thoracolumbar fractures. This system divides the spine into anterior, middle, and posterior columns. The anterior column consists of the anterior half of the vertebral body, the anterior half of the intervertebral disk, and the anterior longitudinal ligament. The middle column consists of the posterior half of the vertebral body, the posterior half of the intervertebral disk, and the posterior longitudinal ligament. The posterior column consists of the posterior arch, the facet joint complex, the interspinous ligament, the supraspinous ligament, and the ligamentum flavum. The spine is considered unstable if two or more columns are disrupted. The Denis classification system does provide for an anatomic description of the zones of injury for thoracolumbar trauma but unfortunately does not account for neurologic status and guide clinical treatment decision.

Holdsworth described the first mechanistic classification of spinal injuries based on experiences of over 1,000 patients by categorizing fractures as simple wedge, dislocation, rotational fracture-dislocation, extension, burst, and shear. This was the first classification to highlight the importance of posterior ligamentous complex (PLC). Allen and Ferguson, later in 1982, proposed a classification of subaxial spine fractures based on radiographic appearance and the inferred
mechanism of disruptions. This classification has six groups including (1) flexion compression, (2) vertical compression, (3) flexion distraction, (4) extension compression, (5) extension distraction, and (6) lateral flexion. Mechanistic classifications have limited clinical application because they are mainly based on inferred mechanisms of injury rather than objective injury morphology. Furthermore, similar to anatomic descriptive classifications, neurologic status of the patient is not included, which is essential in treatment decision-making [7]. Because of the lack of clinical relevance of the previously established classification systems and an overall “gold standard” system, Vaccaro et al. [9] proposed the Subaxial Cervical Spine Injury Classification System (SLIC) and Thoracolumbar Injury Classification and Severity Score (TLICS) [10] system that is based on injury morphology, integrity of the disco-ligamentous complex (SLIC) (Fig. 42.2) or posterior ligamentous complex (TLICS) (Fig. 42.3) and neurologic status. These two systems were designed to incorporate key anatomic and clinical predictors of stability and severity of injury. The goal of these systems is to simplify communication, help guide treatment, and provide a common language upon which further study can be performed.

FIGURE 42.2 Subaxial Cervical Spine Injury Classification System (SLIC) [9].
The three components of the SLIC system include: morphology, discoligamentous complex, and neurologic status. Each component is assigned a weighted score. The overall injury score is the sum of the weighted score of each component. Nonoperative treatment may be considered for a score $<4$, and operative treatment may be considered for score $>4$. If the score $= 4$, then either nonoperative or operative treatment may be considered.

The three components of the TLICS system include: morphology, posterior ligamentous complex, and neurologic involvement. Similar to SLIC system, each component has a weighted score and the overall injury score is the sum of the three components. Nonoperative treatment may be considered for score $<4$, and operative treatment may be considered for score $>4$. If score $= 4$ then, either nonoperative or operative treatment may be considered.

SLIC and TLICS systems are built on three components that are independent determinants of prognosis and optimal treatment. They are the first comprehensive spinal trauma classification systems that account for the neurologic status of the patient. Most importantly, SLIC and TLICS systems overcame the shortcomings of the previous classification systems by demonstrating good interobserver reliability and validity [10]. Furthermore, Patel et al. demonstrated that these systems can be easily
incorporated into large clinical practice with physicians of different levels of experience from attending surgeons to fellows and residents [11].

**Neurologic Injury**

Assessing neurologic injury is the key in determining the level of injury and the severity of injury to the spinal cord. The extent of the injury can determine the treatment options and overall prognosis. Motor examination includes strength measurement (Grade 0–5) of five key upper- and lower-extremity myotomes. The upper extremity myotomes include C5, elbow flexion; C6, wrist extension; C7, elbow extension; C8, long finger flexion; T1, finger abductions. The lower-extremity myotomes include L2, hip flexion; L3, knee extension; L4, ankle dorsiflexion; L5, great toe extension; S1, ankle plantar flexion. Sensory examination is comprised of light touch and pinprick sensation along the dermatomes [12].

The ASIA (American Spinal Injury Association) scoring system [13,14] was proposed to allow for easy classification of neurologic impairment. The scoring system is based on motor, sensory, reflex, and rectal function (Fig. 42.4). For a complete neurologic examination, it is important to consider if the patient is in spinal shock by checking the bulbocavernosus reflex. This reflex is characterized by anal sphincter contraction in response to squeezing the glans penis. Tugging on an indwelling Foley catheter can also elicit the reflex.

**FIGURE 42.4** American Spinal Injury Association (ASIA) scoring system [13] documents the motor and sensory function to determine the severity of the neurologic injury. The motor score is comprised of 10 key muscles groups as seen on the left column of the
The sensory score for light touch and pinprick is comprised of sensation within 28 dermatomes. Perianal sensation and anal contraction assessment is critical to determine the functional preservation in the lowest sacral segments, S4–S5. An AIS (ASIA impairment score) grade is determined based on these neurologic findings.

It is also important to determine the neurologic level of injury. This is defined as the lowest segment with intact sensation and antigravity (grade 3 or more) motor function. In the regions where there is no myotome to test, motor level is presumed to be the same as sensory level. Another key component of the neurologic assessment is to determine whether the injury is complete or incomplete. Complete injury is defined as no anal contraction, 0/5 distal motor score, 0/2 distal sensory score, and present bulbocavernosus reflex. Incomplete is defined as voluntary anal contraction or present perianal sensation, or palpable/visible muscle contraction below the neurologic level.

The ASIA scoring system yields an ASIA Impairment Score (AIS), which groups each injury into five categories (A–E) based on severity (Fig. 42.5). Grade A is a complete neurologic injury with no motor or sensory preserved in the sacral segments (S4–S5). Grade B, C, D are incomplete neurologic injures. Grade B is defined as preserved sensory function but not motor function below the neurologic level and includes the sacral segments (S4–S5). Grade C has preserved motor function below the neurologic level and more than half of key muscles below the neurologic level have a muscle grade less than 3. Grade D has preserved motor function below the neurologic level with at least half of the key muscles below the neurologic level have a muscle grade of 3 or more. Grade E has normal neurologic function.
The AIS has prognostic value for determination. Fisher et al. found that patients with ASIA A (complete) spinal cord injury had no distal lower extremity functional recovery 2 years after the injury. Approximately half of AIS A patients will achieve ambulatory status, compared to ¾ of AIS B patients and almost all patients with AIS C injuries. Younger patients tend to have a better prognosis as well. Burns et al. found 91% of patients younger than 50 years with AIS C were ambulatory at discharge compared to 42% in patients older than 50 years [12,15].

Patients with no motor or sensory function preserved in the lowest sacral segments (S4–S5) are AIS A. Those with sensory sparing in the lowest sacral segments but no motor functions are AIS B. Those with preserved motor function below the neurologic level but the majority of myotomes having a muscle grade of 2 or less are AIS C. Those with preserved motor function below the neurologic level with majority of myotomes having a muscle grade of 3 or more are AIS D. Patients with normal motor and sensory function are AIS E.

There are several incomplete neurologic injuries based on specific locations of the spinal cord that have predictable patterns of neurologic findings.

**Anterior cord syndrome** is characterized by loss of motor and loss of pain and temperature sensation below the level of the injury. Vibratory sense and proprioception are preserved. This is usually a result of flexion/compression injury that lead to either direct compression of the anterior spinal cord or disruption of anterior spinal artery (supplies anterior two-thirds spinal cord). This injury carries the worst prognosis of incomplete SCI.
Central cord syndrome is the most common incomplete cord injury. It often occurs in the elderly with extension type injury mechanisms. It is believed to be caused by spinal cord compression and central cord edema with injury/destruction of lateral corticospinal tract white matter. The classical finding on physical examination is more pronounced motor deficits in the upper extremities compared to the lower extremities. Hands typically have more pronounced motor deficits than arms. This is owing to the fact that hands are more “centrally” located in the corticospinal tract. Patients with central cord syndrome have good prognosis but full functional recovery is rare. Lower-extremities function typically recovers first and hand function is last to recover [16].

Posterior cord syndrome is very rare and examination findings include loss of proprioception with preserved motor, pain and light touch. It is a result of direct injury to the dorsal columns. Stabbing injuries to the back commonly cause this injury pattern.

Brown–Sequard syndrome is a complete cord hemitransection as a result of penetrating trauma or direct lateral injuries to the spinal cord. Patients on examination have ipsilateral deficit in motor, vibratory sense and proprioception below the level of the injury and contralateral loss of pain and temperature sensation. These patients have excellent overall prognosis with the majority of patients able to ambulate at final follow-up.

Conus medullaris syndrome presents with symmetric lower-extremity motor deficits and bowel and bladder dysfunction. Patients typically have symmetric perineal or “saddle” loss of sensation. This is a result of injuries to the conus medullaris at the thoracolumbar junction. Because of the significant amount of nerve roots emerging from this area of the spinal cord, patients are less likely to recover neurologically compared to nerve root injury.

Cauda equina syndrome is defined by symptoms that result from nerve root compression in the lumbosacral region. This is most commonly caused by disc herniation but in trauma patients this nerve root compression can result from retropulsion of fracture fragments or fracture dislocation of the vertebrae. Key features of cauda equina syndrome include bilateral leg pain, bladder and bowel dysfunction, saddle anesthesia, and lower-extremity motor and sensory deficits. Certain lesions may affect the transition level between the conus medullaris and cauda equina, and symptoms may overlap. Cauda equina is predominantly lower motor neuron dysfunction, and deep tendon
reflexes will be intact in the levels cranial to the level of injury. Patients with conus medullaris syndrome have predominantly upper motor neuron dysfunction, and patients will have absent deep tendon reflexes in the lower extremities.

**Pathophysiology**

**Blunt Trauma**

Damage to the spinal cord from blunt trauma injury occurs in two stages. The primary injury phase includes a combination of mechanical factors that cause direct injury to the spinal cord. This leads to direct neurologic dysfunction at and below the level of the injury. This direct mechanical disruption and persistent pressure on the spinal cord leads to secondary events that worsen the initial damage [17].

Within seconds to minutes after the injury (immediate phase), there is disruption of microvasculature that leads to possible hemorrhage in the gray matter, and edema in the white matter of the spinal cord [17,18]. This increases the extracellular fluid and pressure, which leads to decreased perfusion in the spinal cord. This decrease in perfusion ultimately results in ischemia owing to thrombosis and vasospasm [19].

After the immediate phase is the early acute phase, which occurs from 2 hours to 2 days after the initial injury. There is further damage from ionic dysregulation and excitotoxicity. Intracellular sodium concentration increases as a result of trauma-induced activation of voltage-sensitive sodium channels [19]. This increase in sodium is accompanied by influx of calcium through the sodium–calcium exchanger, which leads to intracellular acidosis and cytotoxic edema. Furthermore, this influx of sodium and calcium triggers release of excitatory neurotransmitter glutamate in the presynaptic neurons. This excessive accumulation of glutamate leads to amplification and propagation of depolarization, which eventually leads to postsynaptic neuron edema and death. Furthermore, there is increased infiltration of neutrophils, free radicals, and inflammatory mediators in this phase that contribute to neuronal damage [20].

In the subacute phase, which is from 2 days to 2 weeks postinjury, there is increased phagocytosis and apoptosis of the neuronal cells, and demyelination is followed by cyst formation [20].

**Penetrating Trauma**

Penetrating SCI comprises a distinct mechanism of spinal injury that deserves special consideration. Gunshot wounds and stabbings account for the greatest proportion of penetrating SCI followed by injuries from
falls onto sharp objects and industrial type accidents [21].

Gunshot missiles impart damage in three ways: (1) Direct tissue destruction; (2) Pressure or shockwave effect; and (3) Temporary cavititation. The extent of tissue damage from a gunshot missile is related to the energy imparted by the projectile. Kinetic energy (KE) is calculated based on the equation \( KE = \frac{1}{2} mv^2 \) (\( m \) = mass and \( v \) = velocity). Based on this principle, increases in velocity impart an exponential increase in kinetic energy, which transfers into a greater degree of tissue destruction. In general, guns with muzzle velocity below 2,000 feet/sec are considered “low velocity” (civilian pistols) and those over 2,000 feet/sec are considered “high velocity” (military rifles or assault weapons). Shotguns impart a low velocity but high energy owing to the large mass of the pellets or slug that is delivered. It is important to identify the type of weapons used as it will dictate the extent of soft-tissue damage and help guide treatment. Furthermore, the path which the bullet passes through or comes to a complete stop within the patient can also affect the extent of the damage. Bullets that are jacketed tend to pass through targets, whereas bullets that yaw (wobble) often enter the target at an angle thus resulting in a great cross-sectional area or tissue cavity.

SCI from stabbings involve cervical and thoracic locations in 80% of the cases, and are split equally in prevalence [22]. “Cord hemisection” injury is more commonly seen in stabbing injuries owing to the spinal column bony anatomy. The penetrating object typically finds the path of least resistance in the gutter between the transverse process and spinal process. Because of the orientation of the spinous process (caudal and sagittal), the knife typically is blocked from crossing the midline. This results in Brown–Séquard syndrome with loss of ipsilateral motor and proprioception and contralateral pain and temperature.

**Acute Management**

Early management of a patient with potential spinal cord/spinal column injury should begin immediately at the scene of the accident. Pathologic motion of the injured vertebrae can lead to worsening neurologic injury. It is estimated that 3% to 25% of spinal cord injuries deteriorate neurologically after the initial trauma owing to transit or early management of the patient [12,23]. There has been dramatic improvement in the neurologic status of trauma patients since the establishment of spinal immobilization protocols that stabilize patients from the scene of the accident to the hospital. Current recommendations for spinal immobilization consist of a rigid cervical collar, lateral supports, and tape and body straps to secure the patient to a backboard to immobilize the entire spine. Unwanted motion can still occur during transport or logrolling the patient, resulting in neurologic deterioration.
It also should be emphasized that a rigid cervical orthosis does not eliminate all cervical motion [24].

Physicians should review the details of the accident, the energy and mechanism of injury, and the general condition of the patient at the scene. Patients with closed head injuries and facial trauma should raise suspicion for a cervical spine injury owing to transmission of force. Patients with a “seat belt sign” may have a thoracolumbar spine injury consistent with flexion distraction of the spine about the fulcrum of the seatbelt. Patients who have fallen from height may have lumbar burst fractures with other distracting injuries such as open calcaneus or tibial plafond fractures. Physicians must be aware of certain patient populations such as pediatric patients or adults with preexisting kyphotic deformities that require special attention during prehospital management. In pediatric patients, the head size is disproportionately larger than the body. Anterior translation/flexion injury may occur if the patient is positioned on a flat surface. An occipital recess or a mattress placed under the torso is needed to maintain neutral spinal alignment. In patients with suspected neurologic injury without radiographic (plain radiograph or CT scan) abnormality (SCIWORA), MRI imaging is recommended. In adult patients suspected to have ankylosing spondylitis or diffuse idiopathic skeletal hyperostosis (DISH), physicians must be aware of a preexisting kyphotic deformity as well as the very rigid mechanical nature of their spines [12]. Placing a cervical collar and taping the head to a flat backboard can worsen an extension–distraction injury, resulting in further neurologic damage. Patients with AS and advanced kyphosis may require their heads to be propped up to maintain the preexisting deformities rather than cause an iatrogenic deformity that may lead to neurologic impairment [12].

Initial evaluation of a patient should follow the Advanced Trauma Life Support protocols (ATLS), including Airway (A), Breathing (B), Circulation (C), Disability (D), and Exposure (E). Airway management is essential in the trauma patient. In case of emergent intubation, in-line immobilization and neutral cervical position should be maintained at all times. Patients with neurologic injury at or above C3 often experience acute respiratory arrest and require mechanical ventilation [12]. Lower-level cervical or thoracic injuries may also lead to difficulty with breathing owing to impaired intercostal muscle function. Maintaining oxygenation and perfusion should be a priority in trauma patients. Hypotension should be treated aggressively and the etiology of suspected hemorrhage should be investigated thoroughly. Patients with seatbelt
injures often have intra-abdominal pathologies along with thoracolumbar flexion–distraction injury [12]. Furthermore, one should suspect neurogenic shock in the setting of a hypotensive and bradycardic patient. Neurogenic shock occurs in approximately 20% of cervical spinal cord injuries and is a result of loss of sympathetic tone on the peripheral vasculature [25,26]. Neurogenic shock often occurs with injuries above the T4 level, and hypotension should be aggressively treated to prevent further ischemic cord damage. Pharmacologic interventions should be used in case of hypotension not responsive to fluid resuscitation. Alpha-agonists such as dopamine and norepinephrine can increase peripheral vascular resistance [12].

Radiographic Assessment

The goal of cervical spine clearance is to safely and efficiently rule out an injury that might, if missed, lead to neurologic injury or late instability [12]. Patients with neck pain, tenderness, and neurologic deficits and obtunded patients require radiologic evaluation. Patients who are temporarily cognitively impaired should be protected with spinal precautions until a definitive clinical examination is completed.

Diagnostic imaging modalities utilized to assess spinal column/spinal cord pathologies include plain radiographic films, computed tomography (CT) scans, and magnetic resonance imaging (MRI) scans. Two decision guidelines have previously been established to minimize use of unnecessary imaging in trauma patients. NEXUS Low Rick Criteria [27] (National Emergency X-radiography Use Study) was designed to identify patients who do not need diagnostic imaging to exclude a clinically significant cervical spine injury. Cervical spine radiographs are indicated unless the patients fit all of the following criteria: alert and not intoxicated, no posterior midline tenderness, no neurologic indications of injury, and have no distracting injuries. CCR [28] (Canadian C-Spine Rule) guidance states, “the patients who meet the following criteria do not require radiographic study: fully alert and oriented, involved in low-energy trauma, no neurologic symptoms, no midline tenderness, can actively rotate head 45 degrees in both directions, and have no distracting injuries” (Fig. 42.6).
Plain radiographs provide information on bony integrity and overall alignment. Upright plain radiographs including flexion/extension films are often used to assess spinal column alignment under physiologic load. CT scans provide a more sensitive and specific modality for evaluation of bony pathology. It has enhanced resolution compared to plain radiographs and it allows visualization of the occipitocervical and cervicothoracic junctions.

Patients with a known diagnosis of ankylosing spondylitis or diffuse idiopathic skeletal hyperostosis (DISH) should be treated with extra caution [12]. Owing to fusion of multiple spinal segments (especially in patients with ankylosing spondylitis), nondisplaced fractures behave like diaphyseal long-bone fractures and are potentially highly unstable. Previously mentioned scoring systems to assess stability do not apply to these patients and missed diagnosis can have catastrophic results. Patients with AS who have been in even a minor trauma that have back/neck pain should have CT/MRI to rule out fracture. Negative plain radiographs are not sufficient to make a definite diagnosis [12]. A prior study demonstrated a high rate of neurologic deterioration if fractures are missed in this patient population [29].

Magnetic resonance imaging (MRI) has become the gold standard for imaging neurologic tissues including the spinal cord. When a patient’s...
neurologic examination does not match the fracture pattern seen on CT scan, MRI should be the utilized in the evaluation process. MRI allows better visualization of the spinal cord, ligaments, discs, vessels, and other soft tissues. Patients with cervical spine injuries have high rate of disc herniation (36%) on MRI, along with posterior ligamentous injuries (64%) [30]. Furthermore, MRI allows the surgeon to plan surgically and prognosticate in the setting of spinal cord injuries.

Four MRI imaging patterns of spinal cord injuries have been described, and include normal cord, single-level edema, multi-level edema, and mixed hemorrhage and edema. Patients with single-level edema had overall improvement of two grades in ASIA score compared to an improvement of one for patients with diffuse edema. Single-level edema patients had higher chance of returning to ASIA E grade compared to those with diffuse edema. Patients with edema and hemorrhage have the worst prognosis, with 95% classified as ASIA A at the time of initial presentation. These patients improved one ASIA grade only 5% of the time [30].
TREATMENT

Nonoperative

Patients with SCI often benefit from multidisciplinary nonoperative ICU care. Previous studies have shown improved management and lower morbidity and mortality following acute SCI with ICU monitoring and aggressive medical management \cite{31,32}. Nonoperative SCI care can be categorized into two categories \cite{41}: neuroprotective measures and indirect reduction with immobilization.

1. Neuroprotective measures
   Maintenance of adequate oxygenation and perfusion to the spinal cord may be neuroprotective against secondary SCI. Hypotension in animal models of SCI results in worse neurologic outcome \cite{31}. No prospective controlled assessment of hypotension on human SCI patients has been performed, but previous observational or retrospective studies set a goal for MAP at a minimum of 85 to 90 mmHg based on evidence in the traumatic brain injury (TBI) patient population. Studies of TBI suggest that MAP less than 90 mmHg has been associated with increased morbidity and mortality. Current standard of care management includes support of arterial oxygenation and spinal cord perfusion pressure, and maintenance of MAP above 85 to 90 mmHg for the first 7 days following spinal cord injury is recommended \cite{31}.

   Pharmacologic intervention for spinal cord injury aims to minimize the secondary zone of injury \cite{33}. The most publicized intervention was the use of high-dose methylprednisolone for spinal cord injury. NASCIS \cite{34-36} (National Acute Spinal Cord Injury Studies) II and III studies found extremely modest yet inconsistent neurologic improvement with high-dose methylprednisolone. However, the complication rates were significant and include wound infection, hyperglycemia, GI hemorrhage, sepsis, steroid induced myopathy, and death. High-dose methylprednisolone can also significantly alter immune response with decreased T-cell count, and patients who received treatment are associated with higher rate of pneumonia and longer hospital stays \cite{37}. The authors do not recommend the use of corticosteroid in the setting of traumatic SCI.

   GM-1 Ganglioside (Sygen) is another drug with promising results in
early studies. This compound is found indigenously in cell membranes of mammalian central nervous system tissue and thought to have antiexcitotoxic activity, potentiate the effects of nerve growth factor, and prevent apoptosis. A multicenter study randomized 797 patients within 72 hours of injury to receive either GM-1 ganglioside or placebo. Although patients with ASIA grade C and D SCI treated with GM-1 ganglioside demonstrated significant neurologic improvement compared to placebo-treated patients at 4 and 8 weeks after injury, the advantage was lost at subsequent follow-up visits. No difference was noted in any of the outcome measures at 1 year [37].

A number of promising pharmacologic therapies are currently under investigation for neuroprotective effect in animal models. These include the sodium (Na\(^{+}\)) channel blocker riluzole, the tetracycline derivative minocycline, the fusogen copolymer polyethylene glycol (PEG), and the tissue-protective hormone erythropoietin (EPO) [17,38].

2. Indirect reduction and spinal immobilization
The goals of SCI treatment are to prevent neurologic deterioration, reestablish spinal column stability, and regain neurologic function. Neurologic deterioration is a real risk once the patient has come under the care of medical personal. Understanding the functions and limitations of spine orthoses is critical to limit those occurrences. SCI patients should first be immobilized with bed rest and “spine precautions.” All cervical fracture patients should be protected by cervical orthosis. Previous cadaver studies have shown that specimens with cervical collar had similar cervical spine motion compared to those who did not during bed-to-bed transfer. For this reason, extra caution must be used during patient transfer despite the presence of cervical orthosis.

In patients with high cervical injuries including occipitocervical dissociation, rigid cervical collars may not adequately immobilize those spinal segments. The halo vest remains the orthosis of choice for these patients. A halo vest is the most rigid cervical external immobilizer. It restricts up to 75% of flexion/extension at C1–C2 level and has superior control of lateral bending and rotation compared to other cervical orthoses. Halo vest should not be used in patients with advanced age, chest trauma, cranial fractures, infection, or soft-tissue damage around the proposed pin sites [39].

Certain fracture/dislocations of the cervical spine may require in-line cervical traction with Gardner–Wells tongs to achieve fracture
reduction. The patient should be awake/alert and positioned in reverse Trendelenburg position with shoulder straps attached to the end of the bed. Gardner–Wells tongs are typically applied 1 cm superior to the pinna of the ears. Traction weight should be applied and increased gradually and incrementally. At every step, a neurologic examination and lateral cervical X-ray must be performed. If reduction is successful, a postreduction CT or MRI scan should be done [39].

KTT (kinetic therapy treatment) is a laterally rotating bed created to substitute frequent patient positioning in order to minimize the complications of long-term bed rest. Previous cadaver studies have shown that KTT generated significantly less cervical and thoracolumbar spine motion in comparison to logroll [40]. The author recommends that KTT should be used for initial immobilization for patients with cervical, thoracic, or lumbar instability.

Medical Management of Spinal Cord–Injured Patients

Spinal cord injury may cause dysfunctions in multiple organ systems, leading to increased mortality and decreased quality of life [41]. SCI above T6 vertebra disrupts the descending pathways to the sympathetic neurons in the intermediolateral column of the spinal cord from T1–L2. Loss of sympathetic control results in increased sympathetic activity below the injury and loss of inhibition of parasympathetic nervous system above the level of injury [41].

Sympathetic neurons in the upper thoracic spinal cord (T1–T5) innervate the vessels of the upper body and heart [41]. Neurogenic shock, which is characterized by hypotension and bradycardia, is a result of intact parasympathetic influence via vagal nerve with a loss of sympathetic tone. Treatments of neurogenic shock include fluid resuscitation for hypotension, atropine in the setting of bradycardia, and vasopressors such as dopamine or norepinephrine in the setting of severe hemodynamic instability [31]. Owing to decreased transmission of cardiac pain (T4), patients with SCI above that level may have impaired perception of chest pain in case of ischemic cardiac events [41]. During the acute phase of SCI, vagal nerve disturbance can last 2 to 3 weeks; in certain cases, pacemakers are required to maintain a functional cardiac rhythm [41].

Autonomic dysreflexia is a sudden uncontrolled sympathetic response resulting in uncontrolled arterial blood pressure. This typically occurs in patients with SCI above T6. This is a life-threatening event, with blood pressures above 250 mmHg reported [42]. The incidence of AD was found to be 10% to 11% during the first 3 years postinjury [42]. The most common offending trigger is bladder distention owing to urinary retention or catheter blockage. Other triggers include constipation,
urinary tract infection, and traumatic/painful stimuli. The mainstay of treatment for AD is prevention and avoidance of common triggers. Pharmacologic interventions should include drugs that are rapid-onset with short duration; that is, nifedipine, hydralazine, or sodium nitroprusside [43].

Respiratory insufficiency and pulmonary dysfunction are common after spinal cord injury, especially in the high cervical level owing to phrenic nerve innervation (C3–C5) [31]. Early initiation of vigorous pulmonary therapy after acute SCI is associated with increased survival, reduced incidence of pulmonary complications, and decreased need for ventilator support [31]. Aggressive secretion clearance, pulmonary toilet, and chest physiotherapy are highly recommended to lower the rate of pulmonary complications. In the thoracic spinal cord injury population, the location of injury is a predictor of the incidence of pulmonary complications. Maung et al. found a higher rate of pneumonia in high thoracic injury patients (T1–T6) compared to low thoracic injury patients (T7–T12), 43.3% versus 25.4%, respectively [44,45].

Spinal cord injury often leads to bladder dysfunction. This dysfunction can be classified as either an upper motor neuron or lower motor neuron syndrome [41]. Upper motor neuron syndrome leads to detrusor hyperactivity, where the bladder wall contracts in response to minor stretch without any voluntary external urethral sphincter control. This results in frequent, involuntary voiding. Lower motor neuron syndrome leads to decreased or absent detrusor contractility (flaccidity) with a distended bladder. Bladder management in SCI patients include sterile intermittent catheterization (SIC) in the hospital and clean intermittent self-catheterization outside the hospital [41]. Anticholinergic medications may be helpful with spastic bladder.

The incidence of thromboembolic events in the untreated patients with spinal cord injury is high, ranging from 7% to 100% [46,47]. There is a high rate of morbidity and mortality associated with occurrence of DVT and PEs in this population. Thromboembolic events are responsible for 9.7% of all deaths in the first year following SCI. Furthermore, SCI patients have 500-fold increased risk of PE-related death in the first month following the injury [47]. Previous systematic review has suggested that low-molecular-weight heparin (LMWH) is more effective than unfractionated heparin in preventing DVT in the SCI population [47]. IVC filters are not recommended as a routine prophylactic measure, but are recommended in patients who failed or are not candidates for anticoagulation therapy.
Operative treatment in patients with spine fractures has typically been for unstable fractures, progressive neurologic deficits, and patients unable to tolerate bracing (i.e., obesity, skin lesions, visceral injury, multi-extremity injuries).

The goal of surgical intervention in patients with spinal cord injury is to achieve spinal stability, deformity correction, neurologic recovery, and pain control, and allow for rehabilitation [48]. Surgical decompression and stabilization of the spine can be performed via an anterior, posterior, or combined approach. The anterior approach is indicated when neurologic deficits are caused by anterior compression such as bony retropulsion or disc herniation. This procedure may include corpectomy (removal of a portion of the vertebra and the adjacent intervertebral discs) and strut grafting using allograft, autograft, metal cages, or a combination of these. Corpectomy is usually supplemented with additional posterior instrumentation for increased spinal column stability. The posterior approach can achieve spinal cord decompression by either directly removing retropulsed vertebra through a transpedicular approach or via ligamentotaxis by restoring the vertebral height and alignment with posterior instrumentation.

Optimal timing of surgical intervention to achieve maximum neurologic recovery remains a controversial topic. Most of the studies performed on the timing of surgical decompression is usually classified as early (<72 hours) or late (>72 hours). This time delineation is likely based on preclinical studies that showed that early decompression of acute spinal cord injury could lead to improved neurologic function [49]. Previous data suggest that white matter is more resilient and damage is reversible up to 72 hours after injury, compared to irreversible damage to the gray matter [48]. Unfortunately, in clinical trials, there is no clear evidence to support early surgical decompression in improving neurologic outcomes. Dimar et al. showed no benefit with early surgery compared with late surgery in a randomized controlled trial of cervical spine injury [49]. Cengiz et al. [50] performed a prospective randomized clinical trial on thoracic fractures, which demonstrated a nonsignificant trend toward improved neurologic recovery in the early surgery group.

If the goal of surgery is for spine stabilization only, retrospective studies have shown early surgical stabilization (<72 hours) leading to improved outcome. A review by Bellabarba et al. [51] found seven studies reporting decreased hospital LOS with early stabilization, and decreased ICU stay with thoracic spine stabilization. A literature review by Dimar et al. [49] concluded that when neurologic recovery is not considered an outcome of interest, previous studies have consistently shown shorter hospital LOS, ICU LOS, fewer days on mechanical ventilation, and lower
pulmonary complications in patients who had undergone early stabilization. Early stabilization leads to lower overall cost compared to late stabilization cohorts. Unfortunately, these retrospective studies have many confounding factors including significant associated injuries and baseline patient comorbidities [49].

INTRODUCTION

Trauma continues to be the leading cause of death in the first four decades of life in the US; 130,000–150,000 deaths per year are trauma associated. Thoracic trauma is responsible for 20% to 25% of these deaths. Two-thirds of thoracic-related deaths occur in the prehospital setting, usually due to significant cardiac, great vessel, or tracheobronchial injuries. In a study of over 1,300 patients presenting to a level I trauma center with thoracic trauma, Kulshrestha and colleagues reported an overall mortality rate of 9.4%, with 56% of these occurring within the initial 24 hours. While the two strongest predictors of mortality were a low GCS and increased age, other factors including penetrating injury, liver or spleen injury, long bone fracture, and more than five rib fractures also predicted in hospital mortality [1]. In a study of trauma-related hospital deaths at an urban level I trauma center, Demetriades and colleagues found that penetrating mechanism, age more than 60, and chest AIS >3 to be significant variables were associated with patients who had no vital signs on admission [2].

Overall, motor vehicle collisions account for 70% to 80% of all thoracic injuries. The incidence of penetrating injuries varies widely but is usually more prevalent in urban centers. The majority of thoracic injuries can be treated with careful observation or tube thoracostomy. It is historically reported that 12% to 15% of patients with thoracic injury will require a thoracotomy. In a Western Trauma Association multicenter review, only 1% of all trauma patients required nonresuscitative thoracotomy [3]. With the improvements in prehospital care and transport, more severely injured patients, who would have previously died at the scene, are arriving at the hospital alive. Success of the management for these
injuries rests in having a high index of suspicion for the life-threatening thoracic trauma and prompt recognition and treatment of associated injuries.
INDICATIONS FOR URGENT SURGICAL INTERVENTION

Bleeding

Hemothorax is second only to rib fractures as the most common associated finding of thoracic trauma, being present in approximately 25% of patients with thoracic trauma. Bleeding can arise from the chest wall, lung parenchyma, major thoracic vessels, heart, or diaphragm. A small or moderate-size hemothorax that stops bleeding immediately after placement of a tube thoracostomy and full lung inflation can usually be managed conservatively. However, if the patient continues to bleed at a rate of more than 200 cc per hour, exploration is indicated. In addition, the accumulation of more than 1,500 cc of blood within a pleural space is considered a massive hemothorax that is likely due to larger thoracic vessel injury and is an indication for exploration. If the patient becomes hemodynamically unstable at anytime and an intrathoracic source is suspected, emergent thoracotomy should be performed irrespective of chest tube drainage. A chest radiograph should always be obtained after placing a tube thoracostomy to ensure proper positioning of the tube and complete drainage of the pleural space. Video-assisted thoracoscopic surgery (VATS) can be considered in the stable patient with retained hemothorax or in a stable patient who continues to bleed at a slow but steady rate; however, the surgeon should not hesitate to convert to open thoracotomy if visualization is inadequate or drainage and evacuation of the pleural space is incomplete.

Cardiovascular Collapse

The indications for resuscitative emergency department thoracotomy (EDT) continue to be debated. Penetrating thoracic injuries, specifically stab wounds, have the highest rate of survival. Data for blunt trauma are much less encouraging but should not be used as a deterrent, as there are several functional survivors in most reported series. A retrospective study of 959 patients undergoing resuscitative thoracotomy concluded that EDT in blunt trauma with more than 5 minutes or penetrating trauma with more than 15 minutes of prehospital CPR is futile [4]. A wide range of institutional protocols have been developed. However, evidence indicates that almost all survivors are among the group of patients with penetrating thoracic trauma who have signs of life on arrival [5,6]. These patients generally have not exsanguinated but have a penetrating cardiac...
injury with tamponade, which can often be treated effectively by drainage of the pericardium and repair of the injury. In general, EDT is not indicated in any patients who have no signs of life or in blunt trauma patients who have only cardiac rhythm without pulses, as these patients have likely exsanguinated. When performed, resuscitative thoracotomy should be done early. Discovered tamponade should be released; massive pulmonary bleeding should be quickly controlled with staplers, clamping, or manual compression, and hemorrhage from cardiac wounds should be controlled. With no intrathoracic source, the aorta should be clamped and internal cardiac massage continued.

**Massive Air Leak**

Findings on initial presentation of significant subcutaneous emphysema, persistent pneumothorax after chest tube placement, a subsequent large or persistent air leak, or pneumomediastinum should alert the clinician to the presence of major tracheobronchial injury. This injury is potentially lethal but relatively rare, which was found in only 2% to 5% of patients with thoracic trauma. Significant tracheobronchial injuries may result in a massive air leak, leading to hypoventilation. In this situation, maneuvers to stabilize the patient should include decreasing airway pressures to minimize leak. Contralateral mainstem intubation can also be attempted. Major tracheobronchial injuries generally should be repaired as early as the patient’s condition allows. For patients who are too unstable for surgery, temporizing measures for ventilator support include high frequency oscillator ventilation and independent lung ventilation [7].

**Tamponade**

Cardiac tamponade results when fluid or air collects within an intact pericardial sac, resulting in compression of the right heart with subsequent obstruction of venous return and cardiovascular collapse. Potential findings upon presentation include tachycardia and hypotension, cervical cyanosis, jugular venous distension, muffled heart sounds, and pulsus paradoxus. The diagnosis is confirmed with beside ultrasound, pericardial window, or at the time of emergent thoracotomy. Treatment requires prompt resuscitation and decompression of the pericardium, followed by repair of the bleeding source.
DIAGNOSTICS

Diagnostic imaging plays a key role in the management of patients after chest trauma and has a considerable impact on therapeutic decision-making. The chest radiograph (CXR) has traditionally been and remains the initial imaging study of choice to be obtained in patients with suspected chest injury. In many trauma centers, the thoracic component of the bedside ultrasound (extended FAST exam) is preceding the conventional X-ray as an immediate method of identifying pneumothorax and massive hemothorax [8,9]. Computed Tomography (CT) of the chest, however, is commonly used to more accurately identify the nature and severity of chest trauma. CT can be useful in assessing suspected traumatic aortic, pulmonary, airway, skeletal, and diaphragmatic injuries [10,11]. Magnetic resonance imaging (MRI) on the other hand has a limited role in the initial evaluation of any patient with suspected chest trauma. To undergo an MRI, the patient must be stable, and many trauma patients cannot be scanned because of bulky, mechanical supportive equipment. However, in selected patients who are hemodynamically stable, MRI may be particularly useful for the evaluation of vertebral ligamentous injury and spinal cord injury. Other imaging modalities available to the clinician include echocardiography, angiography, and VATS, which can be both diagnostic and therapeutic when appropriately indicated.

Plain Chest Radiograph

The frontal chest radiograph has traditionally been the initial radiographic study to obtain for the evaluation of patients with suspected chest injury. This study is particularly useful for helping to rule out major injury. Ideally, the radiograph should be obtained with the patient in the upright position because of mediastinal widening that is typically seen in the supine position. Chest radiography has a 98% negative predictive value and is therefore quite useful when normal. However, abnormal findings may be subtle and quite nonspecific. Radiographic findings that may indicate mediastinal injury, such as major aortic disruption, include abnormal contour or indistinctness of the aortic knob, apical pleural cap, rightward deviation of the nasogastric tube, thickening of the right paratracheal stripe, downward displacement of the left mainstem bronchus, rightward deviation of the trachea, and, not uncommonly, nonspecific mediastinal widening. Most life-threatening injuries can be screened by the plain chest radiograph and a careful physical exam. Blunt thoracic injuries detected by CT alone infrequently require immediate
therapy. Rather, if immediate therapy is needed, findings will usually be visible on plain radiographs or obvious on clinical exam. Although a plain upright chest radiograph remains one of the basic imaging studies routinely performed on initial screening, it may be over-utilized. A recent study suggests that in the presence of a normal physical exam in the hemodynamically stable patient, obtaining a routine chest radiograph is actually unnecessary, since it rarely, if ever, changes clinical care [12].

Chest Computed Tomography

CT is highly sensitive in detecting thoracic injuries after blunt chest trauma and is superior to routine CXR for visualizing lung contusions, pneumothorax, and hemothorax, and it can often alter initial therapeutic management for a significant number of patients with suspected chest trauma. It has also been shown to detect unexpected injuries and abnormalities, resulting in altered management in a substantial number of patients when applied appropriately [13]. It can be particularly useful in screening for major intrathoracic aortic injury. In one study, contrast-enhanced CT scanning (“CT angiogram”) was 100% sensitive in detecting major thoracic aortic injury based on clinical follow-up and was 99.7% specific, with 89% positive and 100% negative predictive values for an overall diagnostic accuracy of 99.7% [14]. An unequivocally normal mediastinum at CT, with no hematoma and a regular aorta surrounded by a normal fat pad, has essentially a 100% negative predictive value for aortic injury [14–17]. It has also been shown that CT scanning detects 11% of thoracic aortic injuries that are not detected by routine, plain chest radiography alone [18].

CT scanning can also be useful for detecting hemopericardium and/or hemothorax from any cause, injury to the brachiocephalic vessels, pneumothorax, rib fractures, pulmonary parenchymal contusion, and sternal fractures. It can also be useful for detecting pneumomediastinum caused by interstitial lung injury, bronchial or tracheal rupture (commonly associated with pneumothorax), esophageal rupture, iatrogenic barotrauma from mechanical ventilation, or traumatic intubation. In addition, CT scanning can detect injuries otherwise missed by routine plain radiograph. In one study comparing CT scanning with plain radiography, CT scanning detected serious injuries among 65% of those patients not found to have injury by plain film. These injuries included (in decreasing order of frequency) lung contusions, pneumothoraces, hemothoraces, diaphragmatic ruptures, and myocardial rupture [19]. Even for patients without suspected chest trauma, CT scanning of the abdomen, which commonly includes the lower portion of the thorax, often yields important information when intrathoracic injury is present. In one study, hematoma surrounding the intrathoracic aorta
near the level of the diaphragmatic crura seen on intra-abdominal CT scanning was found to be a relatively insensitive but highly specific sign for thoracic aortic injury after blunt trauma. Therefore, the presence of this sign seen on abdominal CT imaging should prompt more specific imaging of the thoracic aorta to evaluate potential thoracic aortic injury [20]. CT scanning has also been shown to be useful to help define the extent of pulmonary contusion and identify patients at high risk for acute respiratory failure among patients with PaO₂/FiO₂ lower than 300.

Digitally processed 3-D reconstruction views from CT scans have also been shown to be useful for diagnosing and determining the severity of sternal fractures [21]. With the advent of high resolution CT scanners that can reconstruct axial, coronal, and sagittal images, even penetrating diaphragmatic injuries, which are difficult to image preoperatively, can be diagnosed with a relatively high sensitivity and specificity [22].

Despite its usefulness, thoracic CT scanning is not routinely indicated for all patients with chest wall trauma. In addition, although there has been a dramatic increase in the utilization of CT scanning in the last decade, its usefulness for detecting clinically relevant injury has recently come into question, especially for patients with a normal screening plain chest radiograph [23].

Ultrasonography (Extended FAST Exam and TEE)

Over the last 10 years, the traditional Focused Abdominal Sonogram for Trauma or “FAST” exam has evolved to include bedside assessment for thoracic injuries and is now referred to as the extended FAST exam or “eFAST.” This modality can provide immediate real-time assessment for pneumothorax by looking for secondary signs of lung inflation such as “sliding” of pleural surfaces and “comet tails” artifacts at the visceral pleura [8,9]. In some situations, the eFAST lung exam obviates the need for a screening chest X-ray, particularly when the patient is to have a chest CT scan. eFAST can also identify large hemothoraces and can assess the pericardium, identifying hemopericardium and tamponade. The results from eFAST are operator dependent with a significant learning curve. However, the results are reproducible among those trained to use the modality and this has become part of the trauma armamentarium at most centers.

Transesophageal echocardiography (TEE) is rapidly gaining acceptance as an important diagnostic tool available to the trauma surgeon and is showing particular promise in diagnosing traumatic intrathoracic aortic injuries. Although somewhat invasive, its portability makes it a diagnostic
procedure of choice in looking at the heart and great vessels in multiply injured trauma patients particularly in the operating room setting. In one study of 58 patients with thoracic trauma, TEE demonstrated its usefulness in diagnosing thoracic aortic injury and permitted the identification of small lesions not detectable by CT scanning or angiography [24]. TEE has shown to be an important diagnostic tool for examining the thoracic aorta and is valuable for identifying aortic injury among high-risk trauma patients who are too unstable to undergo transport to the aortography suite. When an aortic injury is present, typical findings on the TEE can include aortic wall hematomas, intimal flaps, or disruptions. Several groups have shown TEE to be accurate for identifying aortic pathology after trauma, with its diagnostic efficacy mainly limited by the experience of the person performing the exam [25–27]. In addition, it has been shown to be useful for diagnosing blunt cardiac rupture, when other diagnostic modalities have failed, as well as in diagnosing severe valvular regurgitation intraoperatively following foreign body removal [28,29].

**Angiography**

Thoracic aortography historically has been the gold standard for diagnosing thoracic aortic injury and for defining the extent of the injury and involvement of branch disease, when it is present. Aortography has largely been supplanted by dynamic thin-cut contrast CT scanning or CT angiography [11]. This modality involves a rapid high-resolution CT scan with timed contrast injection and subsequent computerized processing of the study. The accuracy of this study and its specificity in defining the anatomy of the aortic injury has made it more than adequate for planning surgical or endovascular interventions. Aortography is occasionally required for the rare situation when CT scan is equivocal. Diagnosis of aortic injury angiographically is usually made by finding one or more of the following: an irregular or discontinued contour of the aortic lumen, an intimal flap, an aortic dissection, and/or a luminal outpouching (i.e., pseudoaneurysm). Thoracic aortography can detect blunt traumatic aortic injuries with 96% sensitivity and 98% specificity. Angiography is invasive and can have associated complications. The complications associated with arteriography include allergic reactions, renal failure, local puncture site problems, stroke, and even death. Radiographic contrast media cause severe anaphylactic reactions in less than 2% of cases.

**Video-Assisted Thoracoscopic Surgery (VATS)**

The role of thoracoscopy in trauma has been explored by a number of investigators. Prior to the modern video era, Jones et al. described
management of 36 patients with thoracoscopy under local anesthesia as a diagnostic tool to define intrathoracic injuries and to visualize ongoing hemorrhage [30]. Four patients in their series were spared abdominal exploration when the diaphragm was found devoid of injury. More recently, Ochsner et al. [31] and Mealy et al. have demonstrated the usefulness of VATS as a diagnostic tool for the assessment of diaphragmatic integrity among cases of penetrating and blunt thoracic injuries, respectively [32]. VATS has become an acceptable surgical modality in the diagnostic evaluation of suspected diaphragmatic injury and has been shown to have therapeutic benefit when evacuation of clotted hemothoraces is able to be performed in stable patients with penetrating chest injuries [33]. Main indications for VATS include diagnosis of and treatment for diaphragmatic injuries, diagnosis of persistent hemorrhage, management of retained thoracic collections, assessment of cardiac and mediastinal structures, diagnosis of bronchopleural fistulas, and diagnosis of and treatment for persistent posttraumatic pneumothorax. In these situations, VATS has been shown to be a useful alternative to an open thoracotomy for selected patients. In select situations, VATS has been used as the primarily modality of treatment for acute traumatic thoracic hemorrhage meeting the criteria for thoracotomy among hemodynamically stable patients [34]. Because lung deflation with single-lung ventilation is a critical component of the technique, VATS is relatively contraindicated in patients unable to tolerate this. Caution should be used in patients with suspected obliteration to their pleural cavity secondary to previous infection (“pleurisy”) or surgery. VATS should have no role in the management of unstable patients and is relatively contraindicated in those patients unable to tolerate formal thoracotomy for any reason. Whether VATS should be considered as the initial approach in the evaluation of all stable chest trauma patients when an intrathoracic injury is suspected is still debated, and appropriate patient selection remains important.
SPECIFIC INJURIES

Chest Wall

Rib Fractures

Rib fractures are the most common injury to the thorax occurring from blunt trauma and are often associated with other injuries. Rib fractures themselves may cause only minor problems in the young and otherwise healthy; however, they may be a marker of more severe injury, and it may be the underlying pulmonary contusion that often accompanies the rib fracture that may be more clinically relevant. A study by Flagel et al. showed that 13% of those patients in the National Trauma Data Bank who had one or more rib fractures ($n = 64,750$) developed complications including pneumonia, acute respiratory distress syndrome, pulmonary embolus, pneumothorax, aspiration pneumonia, empyema, and the need for mechanical ventilation. They also showed that increasing number of rib fractures correlated directly with increasing pulmonary morbidity and mortality. The overall mortality rate for patients with rib fractures was 10%. The mortality rates were higher ($p < 0.02$) with each additional rib fracture, independent of patient age. This ranged from 5.8% for a single rib fracture to 10% in the case of five fractured ribs. The mortality rates were dramatically higher for the groups with 6, 7, and 8 or more fractured ribs to 11.4%, 15.0%, and 34.4%, respectively [35]. It has been shown that rib fractures occurring in the very young should alert the clinician to possible nonaccidental trauma (NAT). In one study by Barsness et al., rib fractures in children under 3 years of age had a positive predictive value of NAT of 95%, and rib fracture was the only skeletal manifestation of NAT in 29% of the children [36]. With regards to the elderly, it has been shown that there is a linear relationship between age and complications, including mortality. It has been shown that elderly patients with rib fractures have up to twice the mortality of younger patients with similar injuries [37]. In addition, this increase in mortality may begin to be seen in patients as early as 45 years of age when more than four ribs are involved [38]. The location of the rib fracture(s) is also important, as it has been shown that left-sided rib fractures are associated with splenic injuries and right-sided rib fractures are associated with liver injuries. While isolated rib fractures have an associated incidence of vascular injury of only 3%, first rib fractures in association with multiple rib fractures have a 24% incidence of associated vascular injury. A first rib fracture along with findings of a widened mediastinum, upper extremity pulse deficit, brachial plexus injury,
and/or expanding hematoma should prompt work-up for a possible subclavian arterial injury.

Pain control and effective respiratory secretion clearance remain the mainstays of therapy for rib fractures. Adequacy of pain control can be monitored by the ability to perform incentive spirometry. Regional analgesia by epidural or paraspinal catheter is appropriate when narcotics are inadequate to allow adequate lung volumes or are accompanied by unacceptable levels of sedation, particularly among the elderly [39–41]. In Flagel’s study noted above, epidural analgesia was associated with a reduction in mortality for all patients sustaining rib fractures, particularly those with more than four fractures [35]. Since this was not a prospective randomized study, it is difficult to tell if there was a correlation between patients that received epidural catheters having an overall lower injury severity score. However, in one prospective randomized trial by Bulger et al., trauma patients with rib fractures were randomized to either receive epidural anesthesia or intravenous opioids for pain relief, and it was shown that those patients with epidural anesthesia had a lower incidence of nosocomial pneumonia and shorter duration of mechanical ventilation [42]. The number of patients that could receive epidural anesthesia was limited, however, due to strict inclusion criteria. The age of the patient sustaining rib fractures should be taken into account, as well as the location of the fractures. In many protocols, patients with multiple rib fractures and a certain age threshold, anywhere from 55 to 65 years, receive an epidural analgesia proactively as their preferred modality of pain control [39–41].

**Flail Chest**

Flail chest occurs when multiple adjacent ribs are broken in two locations, thereby allowing that portion of the chest wall to move independently of respiration. The anatomic definition of flail chest is the fracture of at least three consecutive ribs in two or more places; however, the clinical or functional definition requires a disjointed, “free-floating” segment of chest wall, which does not contribute to normal ventilatory excursion. This gives rise to the classical “paradoxical respiration” whereby the flail segment is “sucked inward” by the negative pressure of inspiration as the rest of the rib cage moves upward and outward. This is a mechanical problem in which negative pressure generated during inspiration within the thorax is dissipated by movement of the flail segment inward. This movement equalizes the intrathoracic pressure, which would normally be accomplished by the movement of air into the lungs. Despite this mechanical impairment, the major mortality and morbidity of flail chest can be attributed to the usual underlying pulmonary contusion, which leads to a ventilation perfusion mismatch,
contributing to the hypoxia; the pain associated with multiple rib fractures can lead to splinting and contribute to lack of deep breathing, atelectasis, compromised secretion clearance, and further hypoxemia. Fortunately, large segment flail chest occurs relatively infrequently. Flagel et al. showed an overall incidence of flail chest of 3.95% in patients with six rib fractures, 4.84% in those with seven rib fractures, and 6.42% in those with eight or more rib fractures [35].

As for simple rib fracture, pain control remains the main therapy for flail chest so as to allow optimal ventilatory excursion and self-clearance of respiratory secretions” by deep breathing and coughing. Obligatory ventilatory support “internal pneumatic stabilization” of the fractures, first described in 1956, has given a way to selective ventilatory support as needed, with subsequent improved outcomes [42–45]. Surgical stabilization of the chest wall has been shown to be of some benefit with regard to shorter length of ventilator dependency, lower rates of pneumonia, and shorter intensive care unit stays, although this form of therapy is not yet widely practiced [46,47]. A number of proprietary systems for rib fracture fixation have been developed after biomechanical studies of the stresses on ribs en vivo (i.e., Rib-Loc, Acute Innovations, Hillsboro, OR, USA; Biomet System, Jacksonville FLa., USA). The benefits and appropriate indications for rib fracture repair remain to be fully defined. Pain control continues to be an important adjunct in any treatment regimen.

Sternal Fracture

Sternal fractures have been shown to decrease the stability of the thorax in cadavers [48]. They usually occur as a deceleration force during traffic accidents together with blunt force trauma from foreign objects, such as steering wheels, although they have been reported as a complication of CPR, which interestingly was found in 14% of medical autopsy cases that had received chest compressions prior to death [49]. Traffic accidents are the cause of sternal fractures in almost 90% of cases, with approximately 25% of fractures graded as moderately to severely displaced. Approximately 30% of patients will have associated injuries, with craniocerebral trauma and rib fractures being the most commonly associated injuries [50]. Displaced fractures are more likely to have associated thoracic and cardiac injuries and are more likely to require surgical fixation.

However, the majority of patients can be safely observed and even discharged home as long as the following criteria are met: (1) the injury is
not one of the high-velocity impacts, (2) the fracture is not severely displaced, (3) there are no clinically significant associated injuries, and (4) complex analgesia is not required. Most serious complications and deaths that occur among patients with sternal fractures are not due to the fracture itself but rather are related to the associated injuries, such as flail chest, head injury, or pulmonary or cardiac contusion. Although approximately 22% of patients will exhibit electrocardiographic changes, elevated cardiac injury enzymes, or echocardiographic abnormalities, only approximately 6% of patients will exhibit a clinically significant myocardial contusion. In addition to myocardial contusion, other complications of sternal fracture such as mediastinal abscess, mediastinitis, and acute tamponade have all been reported. Indications for operative sternal fixation are certainly not absolute and should be judged individually. Generally accepted criteria include severe pain, sternal instability causing respiratory compromise, and severe displacement. Only a small percentage of patients (2% in one series) actually require sternal fixation [51]. A lack of consensus among surgeons on how to treat these injuries, in addition to a lack of randomized trials concerning their optimal approach, have led to this variability of practice.

Scapular Fracture

Scapular fractures are relatively rare and were once presumed to be an indicator of severe underlying trauma and subsequent higher mortality. They occur in only approximately 1% to 4% of blunt trauma patients who present to a level I trauma center and are associated with a higher incidence of thoracic injury compared to those patients who sustain blunt trauma without a scapular fracture. However, more recent studies have indicated that although patients with scapular fractures tend to have more severe chest injuries and a higher overall injury severity score, their length of intensive care unit stay, length of hospital stay, and overall mortality are not necessarily increased [52,53]. Treatment is usually conservative and, most of the time, aimed at the associated injuries that are commonly present.

Scapulothoracic Dissociation

Scapulothoracic dissociation is an infrequent injury with a potentially devastating outcome. Scapulothoracic dissociation results from massive traction injury to the anterolateral shoulder girdle with disruption of the scapulothoracic articulation. Identification of this injury requires a degree of clinical suspicion, based upon the injury mechanism and physical findings. Assessment of the degree of trauma to the musculoskeletal, neurologic, and vascular structures should be made.
Based upon clinical findings, a rational diagnostic approach can be navigated and appropriate surgical intervention planned. Scapulothoracic dissociation is frequently associated with acromioclavicular separation, a displaced clavicular fracture, subclavian or axillary vascular disruption, and a sternoclavicular disruption. Clinically, patients usually present with a laterally displaced scapula, a flail extremity, an absent brachial pulse, and massive swelling of the shoulder. Vascular injury occurs in 88% of patients and severe neurologic injuries occur in 94% of patients. Many of these patients have poor outcomes and present with a flail, flaccid extremity that usually results in early amputation and have an overall mortality of 10%. One of the most devastating aspects of scapulothoracic dissociation is the brachial plexus injuries that occur, which are typically proximal, involving the roots and cords—brachial plexus avulsions are not unusual. Attempts at repair of complete brachial plexus injuries with grafts or nerve transfers have generally been unsuccessful [54]. Treatment includes arterial and venous ligation to stop exsanguination if present, orthopedic stabilization and consideration for elective above elbow amputation to allow for a more useful extremity if brachial plexus avulsion is present. Overall prognosis for limb recovery is poor.

**Pleural Space**

**Pneumothorax**

This section will only focus on pneumothoraces associated with trauma. For further general discussion of pneumothorax in the critically ill, readers are referred to Chapter 176. For in depth discussion of imaging studies on the topic of pneumothorax, readers are referred to Chapters 11 and 179. A traumatic pneumothorax occurs from either blunt or penetrating trauma, with resultant direct injury to the pleura. Rib fractures may or may not be present. Mechanical ventilation can also be considered a traumatic cause of pneumothorax and has an overall associated incidence of 5%. This incidence increases dramatically in patients with underlying lung diseases, such as COPD or acute respiratory distress syndrome (ARDS). Iatrogenic causes of pneumothorax also occur in the hospital setting. Central-line insertions are associated with a 3% to 6% incidence of pneumothorax.

All types of pneumothorax may progress to tension pneumothorax, which occurs in 1% to 3% of spontaneous pneumothoraces and can occur at any stage of treatment. As tension pneumothorax is a rapidly progressive condition, early identification is essential and immediate decompression should be performed when the clinical suspicion is high. Tension pneumothorax is a clinical diagnosis, and treatment should never be delayed to obtain a confirmatory X-ray. Open pneumothorax is
caused when a penetrating chest injury opens the pleural space to the atmosphere. Negative pressure cannot be generated to inflate the lung on inspiration, leading to a collapsed lung and a “sucking” chest wound. Open pneumothorax is an injury commonly seen on the battlefield. In civilian life, impalement by an object is a common cause. For injuries in which the chest wall wound diameter approaches two-thirds of the diameter of the trachea, air will preferentially enter the pleural space through the wound during inspiration, thereby inhibiting normal ventilation through the upper airway, leading to profound hypoventilation and subsequent hypoxia. Changes in venous return can occur similar to that seen in a tension pneumothorax because the injured side is now at atmospheric pressure, while the normal side has negative pressure, creating a mediastinal shift. This in turn can lead to hemodynamic instability. The presence of a “sucking” chest wound makes the diagnosis obvious. External wound size may not correlate with the degree of compromise, as it is the size of the atmospheric-pleural connection that correlates best.

Treatment includes appropriate resuscitative maneuvers, starting with the placement of a sterile occlusive dressing over the wound to allow effective negative pressure ventilation to resume. If this does not suffice, intubation and positive pressure mechanical ventilation may be necessary to correct the ventilatory and hemodynamic dysfunction. A standard method of coverage involves placing a nonporous dressing over the wound and taping it on three sides, allowing it to act as a one-way valve, allowing air to escape during expiration but occlusive during negative pressure inspiration. A chest tube is routinely inserted at a separate site away from the injury to treat any ongoing air leak that might arise from concurrent lung injury. The wound should be treated with local measures and associated injuries should be sought and treated appropriately.

**Hemothorax**

After rib fractures, hemothorax is the second most common complication of chest trauma. It can be caused by bleeding from anywhere in the chest cavity, including the chest wall, lung parenchyma, major thoracic vessels, heart, or diaphragm. It presents in approximately 25% of patients with chest trauma. Patients with hemothorax typically have decreased breath sounds and dullness to percussion over the affected side with associated dyspnea and tachypnea. Depending on the amount of blood loss, they may have hemodynamic changes. The major cause of significant hemothorax is usually due to a laceration to the lung or bleeding from an
injured intercostal vessel or internal mammary artery. Radiographic films may not reveal a fluid collection of less than 300 mL. Small hemothoraces usually resolve within few days. Accumulation of more than 1,500 mL of blood within a pleural space is considered massive, is more commonly seen on the left side, and is usually due to aortic rupture (blunt trauma) or pulmonary hilar or major vessel injury (penetrating trauma). Severe blunt trauma where highly displaced rib fracture fragments puncture deep into the lung parenchyma may also lead to a massive hemothorax. Massive hemothorax can lead to hemodynamic instability including hypotension and circulatory collapse. Neck veins may be flat or distended, depending on whether or not blood loss or increased intrathoracic pressure predominates. A mediastinal shift with tracheal deviation is typically opposite from the side of blood accumulation.

Treatment for acute hemothorax includes supplemental oxygen therapy and, in most cases, the insertion of a large bore (i.e., 32 to 36 French) tube thoracostomy anterior to the midaxillary line at the fifth or sixth intercostal space. A moderate-size hemothorax (500 to 1,500 mL) that stops bleeding immediately after a tube thoracostomy can usually be managed conservatively with a closed drainage system. Bleeding from pulmonary parenchymal injuries that do not involve the hilum usually will stop spontaneously because of the low pulmonary pressures and high concentrations of tissue thromboplastin within the lung [55]. If, however, the patient continues to bleed at a rate of 100 to 200 mL per hour, then exploration is indicated. Likewise, if the patient bleeds out more than 1,500 mL initially through the chest tube, exploration is indicated. VATS exploration has been successfully utilized to control acute thoracic bleeding in patients who are stable [34]. If the patient is hemodynamically unstable at any time, and intrathoracic bleeding is suspected as the cause, emergent thoracotomy should be done regardless of chest tube output. A chest radiograph should always be obtained after placing a tube thoracostomy to check position of the tube and to make sure that the pleural space is adequately drained.

Once the patient is stable and acute bleeding has ceased, retained hemothorax may still be a problem when a large amount of retained blood and clot remains within the pleural space for 24 to 48 hours after tube thoracostomy, semielective exploration with open evacuation should be considered. VATS is an option for the stable patient with retained hemothorax. However, the surgeon should not hesitate to convert to an open thoracotomy if visualization is inadequate or drainage and evacuation of the pleural space is incomplete. If the retained hemothorax is not massive, nonoperative therapy can be considered as these may lyse with time. Alternatively, it has been shown that a retained hemothorax can be successfully treated with instillation of thrombolytics into the
pleural space. This has been deemed safe even for patients who have sustained multiple trauma \[56\]. However, the use of thrombolytics for trauma patients remains debated with some reports of reactivation of thoracic bleeding after instillation of thrombolytics into the pleural space.

**Lung**

**Pulmonary Contusion**

Pulmonary contusion is a common injury found among patients sustaining blunt chest trauma, with an approximate incidence of 30% to 75%. Mortality is between 10% and 25%. Hemorrhage and interstitial edema result from injury to the lung. This can lead to alveolar collapse and the typical parenchymal consolidation seen on the radiograph. Injury to the parenchyma from blunt force trauma is thought to be caused by a combination of events that includes alveolar stretching, parenchymal tearing, and concussive forces. Lung injury in the absence of identifiable rib fractures typically exhibits diffuse injury, whereas rib fractures and flail chest are associated with more localized injuries. The extravasation of blood into the alveolar space causes subsequent consolidation, which can then lead to an intrapulmonary shunt. A flail chest may be associated with pulmonary contusion(s) approximately three-fourths of the time, which more than doubles the morbidity and mortality. Hypoxemia, although nonspecific, is the most common clinical finding associated with pulmonary contusions. Typical chest radiographic findings in the appropriate clinical setting remain the mainstay of diagnosis. Typical findings usually demonstrate a focal or diffuse consolidative process that does not typically follow anatomical segments or lobes. Rib fractures are the most common bony injuries seen and should raise suspicion for the diagnosis of pulmonary contusion, even if other clinical signs are absent at the time. While the respiratory effects of pulmonary contusion may occur soon after injury, they may not become radiographically apparent for up to 48 hours postinjury, with an average delay of 6 hours. On the other hand, CT scanning of the chest has been shown to be able to demonstrate the presence of pulmonary contusion almost immediately postinjury \[57–60\]. In addition, it can help estimate the total volume of injured lung present. This can be helpful for predicting the need for eventual ventilatory support. It has been shown that when pulmonary contusion involves 28% or more of the total lung volume, essentially all patients eventually require mechanical ventilation, whereas when 18% or less of the lung volume is involved, the need for mechanical ventilatory support is unlikely \[61\]. Treatment for pulmonary contusion is generally supportive. Close respiratory monitoring and frequent clinical examination is important, as approximately half of all respiratory failures
secondary to pulmonary contusion occur within the first few hours postinjury. Once coexistent injuries are treated, and the need for emergent surgery is ruled out or performed as required, the patient with pulmonary contusion should be transferred to a monitored bed. Optimal respiratory secretion clearance should be employed and may be achieved through several mechanisms, including airway suctioning, chest physiotherapy, and postural drainage. This helps to minimize atelectasis and clear respiratory secretions. If patients are still unable to clear their secretions adequately, bronchoscopy can be helpful. Adequate analgesia for associated chest wall injuries is also important for maintaining adequate secretion clearance as the effects of the contusions and chest wall injuries are additive. Pain control can be achieved through systemic opioids or regional analgesia. Preferred methods of regional analgesia include nerve blocks, and epidural or paravertebral catheters. Inadequate analgesia as determined by low vital capacity (<15 mL per kg in otherwise healthy individual) or oversedation from opioids are indications for regional analgesia [39–41] (see section “Rib Fractures” above).

Mechanical ventilation can minimize edema and increase functional residual capacity, which in turn can decrease shunt and reduce hypoxemia. Positioning patients with the injured lung in the nondependent position may also improve oxygenation, especially in those patients refractory to other measures. Fluid administration should be done judiciously, as hypervolemia may worsen fluid extravasation into the alveolar spaces and increase parenchymal consolidation, because capillary permeability is already compromised. However, under-resuscitation should also be avoided, as this may lead to thickened secretions and possible systemic effects if hypovolemia occurs. Obviously, fluid administration in these patients can be a difficult balancing act, and good clinical judgment is important. Positive end expiratory pressure (PEEP) should be maintained at the minimum value necessary to ensure adequate oxygenation, because excessive PEEP may actually worsen gas exchange and can actually extend the area of injury. Atelectasis can allow to bacterial growth that can lead to pneumonia, which typically develops several days after the injury. Pulmonary infections may develop in up to 50% of patients with pulmonary contusions. While used by some, diuresis has not been shown to decrease hypoxia or ventilator days in pulmonary contusion when cardiogenic pulmonary edema is not concurrent. Acute respiratory distress syndrome (ARDS) can complicate pulmonary contusion in 5% to 20% of cases, and respiratory dysfunction is a common sequela. Dyspnea may affect as many as 90% of patients during the first 6 months postinjury. In addition, functional reserve capacity has been found to be diminished as late as 4 years after injury, with the majority of patients demonstrating subtle changes on CT [62].
Tracheobronchial Injury/Lung Laceration

Tracheobronchial injury can be a challenge to diagnose, manage, and definitively treat. The true incidence of tracheobronchial injury is difficult to establish, as a large proportion (30% to 80%) of these patients will die before reaching the hospital. It is estimated on the basis of autopsy reports that 2.5% to 3.2% of patients who die as a result of trauma may have associated tracheobronchial injury [63,64]. More than 80% of tracheobronchial injury due to blunt trauma is located within 2.5 cm of the carina. Resuscitation of a patient with tracheobronchial injury can be difficult, since obtaining adequate ventilation may require novel approaches to securing the airway. Patients with tracheal or bronchial injuries make this initial assessment particularly challenging. The majority of patients with tracheobronchial injury seen in the emergency department have some degree of respiratory difficulty and require emergent measures to secure and control the airway, but some may have an initially innocuous presentation with subtle signs. However, several abnormalities can alert the physician to the diagnosis. Tachypnea and subcutaneous emphysema are common. Pneumothorax may or may not be seen on a plain radiograph. The liberal use of bronchoscopy is mandatory for identifying tracheobronchial injuries and constitutes the gold standard in diagnosis. Findings that can typically be seen on bronchoscopy include obstruction of the airway with blood and inability to visualize the more distal lobar bronchi because of collapsed proximal bronchi. Visualization of a bronchial tear is confirmatory.

Orotracheal intubation is the most common method used for airway control. If possible, the intubation should be done over a fiber optic bronchoscope so that the injury can be identified, avoided, and clearly bypassed with the endotracheal tube. It should be noted that merely identifying the glottic opening and vocal cords does not ensure proper placement of the endotracheal tube as there may be complete discontinuity distally. Patients with cervical injuries and open neck wounds can be intubated through the open wound to secure the airway if necessary.

Associated injuries are common and are usually related to the mechanism and location of the tracheobronchial injury. The injury most commonly associated with penetrating tracheobronchial injury is esophageal perforation. Most repairs of cervical tracheal injuries are approached through a collar incision. For patients with injuries high in the mediastinal trachea or with suspected great-vessel injury, a median sternotomy may be necessary. When the injury is associated with a unilateral pneumothorax or a bronchial injury is diagnosed
preoperatively, an ipsilateral posterolateral thoracotomy is the incision of choice. For injuries to the mediastinal trachea, an approach by a right posterolateral thoracotomy (usually high through the fourth intercostal space) is reasonable. Since the initial report by Shaw and colleagues, primary repair of the injured tracheobronchial tree has been encouraged [63,65–69]. Most patients can undergo primary repair of their tracheobronchial injury using tailored surgical techniques specific to the injury. When a major bronchus is disrupted, lobectomy is the preferred method of treatment, with closure of the bronchial stump debrided back to healthy tissue. With injuries to the mainstem bronchi, primary repair is preferred over pneumonectomy whenever possible, due to the higher mortality associated with pneumonectomy, especially in the trauma setting. Injury to the trachea can be either primarily repaired or converted to a tracheostomy if necessary for airway control. Nonoperative management of tracheobronchial injury has been reported to be successful in selected cases. Those patients that seem most appropriate for this approach are those with membranous injuries. Patients that have cartilaginous injuries are more likely to require operative repair. Tracheobronchial injury encompasses a heterogeneous group of injuries that requires skillful airway management, careful diagnostic evaluation, and operative repairs that are often creative and necessarily unique to the given injury.

Heart

Blunt Cardiac Injury

Blunt cardiac injury, formerly referred to as myocardial contusion, is now recognized as a continuum of injury from minor contusion through fatal cardiac rupture [70–73]. Most blunt cardiac injuries are not serious. However, moderately severe cardiac injuries may cause arrhythmias or result in low-output cardiac failure. The clinical significance of myocardial contusion following blunt thoracic trauma is still largely unknown. In one study by Lindstaedt et al., approximately 20% of patients who were admitted to a surgical intensive care unit because of their injuries met the criteria for diagnosis of myocardial contusion [74]. Their criteria include exclusion of pathologic findings on ECG known to be present prior to injury; echocardiographic evidence of a kinetic wall motion abnormalities; combination of regional wall motion abnormality, significant isoenzyme elevation (CK-MB > 7%), and ECG abnormality; regional wall motion abnormality in the baseline echocardiogram and in the control echocardiogram at follow-up; or confirmation of myocardial contusion at autopsy or intraoperatively. Even though the prevalence of the injury was significant in their population, the overall prognosis was
excellent, and the authors recommend that specific diagnostic and therapeutic measures should be limited to cases where cardiac complications develop. The combination of a normal ECG and normal serum troponin levels, drawn at the time of presentation and 8 hours later, essentially rules out significant myocardial contusion and is sufficient, in the absence of other reasons for hospitalization, to discharge such patients safely home [75]. However, patients with an abnormal ECG and elevated troponin should be monitored for at least 24 hours. Cardiac contusion may lead to cardiogenic shock resistant to inotropic support. The use of intra-aortic balloon counterpulsation as a mechanical means of augmenting cardiac function following cardiac contusion is rarely indicated but has been reported with success even in elderly patients [76].

At the other end of the severity spectrum, high energy injuries to the heart can result in cardiac rupture. Atrial and/or ventricular rupture can occur, leading to profound hemodynamic compromise. Rapid recognition of such injuries is necessary for successful treatment. Associated injuries are common and include closed head injury, pulmonary contusion and/or laceration, multiple rib fractures, liver and spleen injury, and traumatic aortic injury; these account for approximately 25% of fatalities seen in patients after blunt cardiac injury. The usual clinical presentation of cardiac rupture is cardiac tamponade secondary to hemopericardium, although less than 15% of these patients actually manifest physiological evidence of tamponade. Associated pericardial tears may allow for decompression of intrapericardial hemorrhage through the pleural space, preventing the development of cardiac tamponade but leading to exsanguinating hemothorax. Pericardial rupture is rare, but can occur in isolation or with associated injuries such as blunt cardiac or diaphragmatic rupture, which has a high mortality. Hypotension is usually present, and the diagnosis of cardiac rupture should be considered in any patient who has hypotension in the absence of overt blood loss. The chest radiograph may not show evidence of cardiac injury, even in the face of tamponade and hemodynamic compromise, since a rapid accumulation of blood into the pericardial space can occur without significantly altering the cardiac silhouette. The Extended FAST ultrasound exam can be useful in diagnosing pericardial tamponade. Diagnosis of blunt cardiac rupture should be strongly suspected when hemopericardium is seen by ultrasound in the setting of blunt trauma. The diagnostic dependability of pericardiocentesis is limited in the assessment of traumatic hemopericardium and potential cardiac rupture because of significant false-negative and false-positive results.
Performing a pericardial window in the operating room, however, can be both diagnostic and therapeutic, and it can confirm hemopericardium and allow for rapid decompression and median sternotomy. Nevertheless, the diagnosis of blunt cardiac rupture requires a fair degree of clinical suspicion, particularly in the setting of hypotension that does not respond to adequate volume resuscitation. Perchinsky et al. reviewed a consecutive series of 27 patients seen between 1984 and 1993 with blunt cardiac rupture. Overall survival rate was 41%. Of note was that three out of nine (33%) patients presenting to the emergency department with no identifiable blood pressure or viable electrical heart rhythm survived resuscitation, surgery, and initial hospital care. No patient survived rupture of two or more cardiac chambers in their series, however [77]. Although cardiac exploration should be performed with cardiopulmonary bypass support nearby, repair of cardiac rupture does not necessarily require its use.

**Cardiac Valvular Injuries**

Blunt cardiac injury may rarely result in valvular insufficiency. The right ventricle is immediately behind the sternum, which makes it particularly vulnerable to injury. Acute severe elevation of right intraventricular pressures has been shown to result in injury of the tricuspid valvular apparatus [71,78]. The most common injury is chordal rupture, followed by rupture of the anterior papillary muscle and leaflet tears. Posttraumatic aortic valve regurgitation has also been reported and affects all ages and is often found in association with sternal or multiple rib fractures [79]. Traumatic mitral valve insufficiency has been shown to present with either complete papillary muscle avulsion from its ventricular attachment or with chordal tears and/or leaflet damage. Those with papillary muscle avulsion typically present with severe regurgitation. Those patients with less severe injuries to the mitral valve, such as chordal tears and/or leaflet damage, usually present with less severe symptoms and may even be asymptomatic. Not only can blunt cardiac injury cause acute valvular incompetence, but it can also predispose patients to delayed valvular dysfunction. In a study performed by Ismailov et al. looking at hospital patient discharges, patients who sustained blunt cardiac injury had an associated 12-fold increased risk for developing tricuspid valve insufficiency and a 3.4-fold increased risk of developing aortic valvular insufficiency later in life, which appeared to be independent of age, race, sex, and injury severity score [80]. There was no correlation found with increased risk for mitral valve insufficiency, however. Traumatic valve insufficiency, depending on severity and valve involved, may necessitate surgical treatment.
Penetrating Cardiac Injury

The clinical presentation of penetrating cardiac injury ranges from one of hemodynamic stability to complete cardiopulmonary arrest. Beck’s Triad represents the classical presentation of the patient arriving in the emergency department in pericardial tamponade and includes venous hypertension with distended neck veins, arterial hypotension, and muffled heart sounds. Kussmaul’s sign: jugular venous distention seen with expiration is another classic sign attributed to pericardial tamponade, though it may not necessarily be appreciated in the acute trauma setting. The physiology of pericardial tamponade is related to the relative inelastic and noncompliant pericardium. Sudden acute loss of intracardiac blood volume into the pericardial sac leads to an acute pressure rise and compression of the thin-walled right ventricle and atria. This decreases the heart’s ability to fill, resulting in decreased left ventricular filling and ejection fraction, thus decreasing cardiac output. Subxiphoid pericardial window remains the gold standard for the diagnosis of cardiac injury, though today more cases are being diagnosed almost immediately upon patient arrival by the Extended FAST ultrasound examination. Jimenez et al. showed that echocardiography had 90% accuracy, 97% specificity, and 90% sensitivity in detecting penetrating cardiac injuries [81]. The usefulness of the FAST cardiac echo may be in its ability to identify obvious hemopericardium, thereby allowing the trauma surgeon to proceed directly to median sternotomy and thus eliminating the need for a subxiphoid pericardial window in many cases.

Pericardial window can also be therapeutic and can be done under local anesthesia in the operating room to allow release of tamponade prior to the induction of general anesthesia. If blood is found, then the surgeon can proceed immediately to median sternotomy and cardiorrhaphy. For relatively stable patients who do not require emergency room thoracotomy, median sternotomy is the incision of choice to repair penetrating cardiac wounds [82,83]. TTE has clearly emerged as the technique of choice for the diagnosis of penetrating cardiac injuries.

Suspected or proven pericardial tamponade with loss of vital signs due to penetrating thoracic trauma is the major indications to perform EDT [6]. An anterolateral thoracotomy is typically performed in between chest compressions and should be extended through all of the subcutaneous tissues, as well as the anterior chest wall muscles, until the intercostal space is identified. Typically, the patient’s vital signs quickly return to acceptable levels. Internal defibrillation may be necessary, as the heart is often found to be in ventricular fibrillation. Epinephrine and similar drugs should specifically be avoided, as release of the tamponade is usually more than sufficient to allow the patient’s vital signs to return.
Epinephrine can increase chronotropy, inotropy, and intraventricular pressures, which can potentially extend ventricular injuries and make repair difficult and unnecessarily challenging. If sinus rhythm cannot be restored despite all attempts, the prognosis is grave and the outcome is invariably poor. Once vital signs are reestablished, attention can then be given to repairing the cardiac injury. Definitive cardiac repair does not necessarily have to be done immediately, however, and in some cases may be ill-advised when performing an emergency room thoracotomy, since it is the tamponade and not the blood loss per se that causes hemodynamic collapse. Once the tamponade is released, digital pressure can be directly applied to the cardiac wound which is often all that is needed once vital signs are restored to maintain relative hemostasis until definitive repair can be done in an operating room. In the authors’ opinion, the use of adjunct measures, such as balloon tamponade with a Foley catheter, can be fraught with creating more injuries or extending existing myocardial lacerations and should be avoided if possible. Vascular clamps can be placed on bleeding right atrial wounds but usually are not necessary and may cause more harm than not, extending small injuries into larger ones. In addition, cross-clamping of the thoracic aorta is generally not necessary and ill-advised with isolated penetrating cardiac wounds. If necessary, it can be temporarily occluded digitally against the bodies of the thoracic vertebrae until adequate resuscitation has taken place. An attempt should be made to trace the trajectory of the wounding agent, as missiles often enter into one thorax and then enter the contralateral hemithorax. Once the tamponade has been released, the patient has regained a rhythm and a blood pressure, and the bleeding sites are identified and digitally controlled, the experienced surgeon can then attempt closure of the cardiac wound in an appropriate equipped operating room. Total inflow occlusion of the heart can be done if the blood loss is substantial through the wound and proper placement of sutures difficult in the face of ongoing blood loss without the aid of cardiopulmonary bypass. This maneuver is performed by placing caval tapes around both the superior and inferior vena cavae within the pericardium, which, when tethered, results in immediate emptying of the heart. The tolerance of the injured heart to this maneuver is limited, however, and should be used only for short periods if found to be necessary. This procedure can result in cardiopulmonary arrest and ventricular fibrillation, and appropriate plans should be made prior to caval occlusion should this happen. Atrial injuries can be repaired with running 2-0 Prolene. Ventricular wounds may be repaired while digitally occluding the laceration while placing a horizontal mattress stitch with a pledget surrounding the wound, usually with 2-0 Prolene. Repairing cardiac injuries resulting from gunshot wounds can be more challenging when compared with stab wounds, since they tend to have associated
blast effects, which can make repair difficult. The repair of ventricular wounds adjacent to or involving coronary arteries can be challenging. If the coronary artery is injured itself but is quite distal (e.g., distal 1/3 of the left anterior descending artery), simple ligation can be done without serious consequences. However, if the injury is more proximal than this, ligation of the injury with distal bypass using a segment of saphenous vein or mammary artery is recommended. This can be done on or off cardiopulmonary bypass but usually requires the expertise of an experienced cardiac surgeon to perform. If the injury does not involve the coronary artery but is in close proximity, suturing of the injury may require placement of a horizontal U-stitch underneath the bed of the coronary artery, thereby closing the injury without compromising coronary blood flow. Patients who have sustained injury to their coronary artery who has already sustained irreversible myocardial damage may require intra-aortic balloon counterpulsation as part of their resuscitation.

Recently, some cases of hemopericardium due to penetrating trauma have been managed by urgent, rather than emergent surgery for stable patients [84].

**Esophagus**

Iatrogenic injuries to the esophagus are the most common, particularly those of iatrogenic esophageal perforation. Traumatic injury and Boerhaave’s syndrome account for most of the rest. Patients who present with esophageal perforation usually complain of pain. Findings may include fever and subcutaneous or mediastinal air. Crepitus in the neck is relatively common following perforations of the cervical esophagus and can be detected on physical exam in approximately 60% of patients. Pleural effusions are present in more than 50% of patients with perforations of their thoracic esophagus. Radiologic studies are important for diagnosing patients with esophageal perforation. A plain chest radiograph may show subcutaneous emphysema, pneumomediastinum, pleural effusion, pneumothorax, or mediastinal air–fluid levels (hydropneumothorax). Radiographic abnormalities can be found in as many as 90% of patients on plain film. Contrast studies are performed to confirm the diagnosis of perforation and to define the exact site. The appropriate type of contrast agent to use for this study remains controversial. Water-soluble contrast agents such as Gastrografin have been the preferred agents of choice since if leakage
through the perforation occurs, they will not seed the mediastinum with particulate matter that serves as a nidus for infection. However, Gastrografin can cause severe pneumonitis if aspirated into the lungs, and its use may not demonstrate small leaks. Because of this, some prefer to use thin barium, as it is more inert in the lungs and is better at detecting smaller leaks. CT scanning can be particularly helpful for showing mediastinal findings such as air, inflammation, and fluid collections when the perforation has already sealed.

The optimal management of esophageal perforation is patient specific and should take into account the clinical setting [85]. This includes consideration of the patient’s underlying disease process, the degree of sepsis, if any, the location of the perforation, and whether or not the perforation is contained. A nonoperative approach may be considered for patients with minimal symptoms and physical findings who do not appear septic and have a small, contained leak. Nonoperative management should include the use of broad-spectrum intravenous antibiotics and nothing to eat or drink by mouth (NPO). A nasogastric tube should be specifically avoided. There is no clear consensus as to generally how long a patient with a contained leak should be left NPO or how long intravenous antibiotics should be continued. However, clear liquids can usually be safely started within a few days and the diet advanced cautiously, especially when no further extravasation is seen on repeat contrast study.

Surgery should be performed if the patient appears septic, the leak freely communicates with either the peritoneal or thoracic cavities, or there is an associated mediastinal abscess. Primary repair can be done regardless of the timing of the injury, as long as the tissues appear healthy at the time of surgery. Drainage alone can be done for cervical perforations, especially if the perforation cannot be found at the time of operation, which is not infrequent. Primary repair with drainage is the preferred method when possible; however, if the esophageal tissues do not appear viable to hold sutures, drainage alone, with or without proximal diversion may be necessary. It is important when primarily repairing the esophagus that the mucosal edges are defined, as the injury seen in the muscle layer is often only the “tip of the iceberg,” and closure of the entire mucosal defect is necessary if adequate healing is to occur.

Esophagectomy is rarely necessary or safe in the acute trauma setting. If resection must be done, diversion should be done and esophageal reconstruction deferred until sepsis and the acute catabolic state have resolved. In these cases, it is better to create an end cervical esphagostomy and oversew the gastric stump with the placement of and enteral feeding catheter. Esophageal injuries due to penetrating trauma are rare, with most series averaging only a handful [86–88]. They result most commonly from transmediastinal gunshot wounds. Asensio et al.
reported their experience consisting of 43 penetrating esophageal injuries managed over a period of 6 years. Overall, 28 of their 32 survivors (88%) were managed by primary repair alone [89]. The overall mortality for their series was 26%. The authors also reported that these mortality figures were consistent with others reported in the literature, which have remained high and relatively stable for the last 20 years, thus attesting to the critical nature of these injuries. Only Symbas et al. (48 cases) and Defore et al. (77 cases) have reported larger experiences but over much longer spans of time, 15 and 22 years, respectively [86,87]. Penetrating esophageal injuries are not easily detected and require a high index of suspicion. Delay in diagnosis is associated with higher mortality. However, mortality can exceed 20% even for patients who are promptly diagnosed. Esophagoduodenoscopy (EGD) is a sensitive and safe diagnostic test for the detection of esophageal injury. A study by Flowers et al. showed that EGD had a sensitivity of 100%, a specificity of 96%, and an accuracy of 97% in detecting penetrating esophageal injuries [90]. There was no morbidity related to the examination, and, most importantly, no esophageal injuries were missed. The authors commented that the most significant potential weakness of flexible EGD for esophageal trauma is that it actually may be too sensitive. EGD is most helpful in excluding esophageal injury in patients who require a surgical procedure for another injury. When found, prompt primary repair is the treatment of choice.

Caustic Injuries of the Esophagus

Caustic injuries of the esophagus can be very challenging to manage. They are most frequently due to suicide attempts in adults and accidental ingestion in children. The degree of injury to the esophagus is directly proportional to the amount of caustic substance ingested. Lye causes transmural liquefaction necrosis of the esophagus and therefore is most injurious. Diagnosis is usually from history, although patients attempting suicide may present with no history at all or, even worse, an inaccurate one. Examination of the buccal mucosa, mouth, tongue, and gums can often show chemical burns suggestive of the diagnosis. Endoscopy should be performed to document the proximal extent of the injury only; there is no need to pass the endoscope further, since it may actually be harmful and potentially lead to perforation. Passage of an NGT is controversial, although it may actually help to “stent” the esophagus open and be associated with lower rates of stricture formation. Arterial blood gases should be obtained with particular attention paid to the base deficit, as
this can be a marker for severity of injury. Signs and symptoms of perforation and sepsis should be carefully monitored. The patient should be made NPO, and broad spectrum intravenous antibiotics should be given. Steroids are controversial but have been associated with lower rates of stricture formation in some series [91,92]. Intravenous fluids should be given and consideration given to performing esophagectomy, if signs of perforation and mediastinal sepsis are present. Intra-abdominal perforations can also occur, as well as injury to surrounding structures (e.g., spleen, colon). If esophageal resection becomes clinically indicated due to sepsis, immediate reconstruction is ill-advised. Esophagectomy can be performed either transhiatally or transthoracically, with creation of an end cervical esophagostomy. Intra-abdominal feeding tubes should be placed for enteral access. Delayed reconstruction can then be performed electively once the sepsis clears and the patient heals, usually several months later. Late stricture formation is common and can be difficult to manage. In addition, the pharyngeal phase of swallowing can be affected, leading to debilitating problems with speech and swallowing. It is not uncommon to require serial dilations or even late esophagectomy if stricture formation develops. It typically involves long segments of the esophagus and is panmural in depth, often making dilation impossible or at best marginally effective. Overall prognosis is variable depending on the degree of injury.

**Thoracic Aortic Injury**

Traumatic disruption of the thoracic aorta immediately leads to death in majority of the patients and is a common finding of autopsy series from high-speed motor vehicle accidents. These horizontal acceleration/deceleration injuries usually result from a disruption of the integrity of the aortic wall just distal to the ligamentum arteriosum. Patients fortunate enough to survive initial injury usually do so because the aortic adventitial tissues are able to tamponade the tear, thereby creating an expanding pseudoaneurysm and thus preventing or delaying fatal intrathoracic exsanguination. The risk of rupture is dependent on multiple factors, including the ability of the adventitial tissues to contain the leak, the patient’s systemic blood pressure, and the size of the contained pseudoaneurysm.

While emergent operative repair of thoracic aortic tears has long been the standard of care, after 1997 there has been emerging evidence that not all thoracic aortic tears should be treated equally. In addition, associated injuries such as pulmonary contusions, intracranial hemorrhage, and/or intra-abdominal hemorrhage (which are common in these patients) may take precedence and may render major aortic surgery particularly hazardous. For these cases, the aortic injury can be acutely
managed medically and definitive treatment delayed, so long as certain criteria are met. With careful medical management (strict blood pressure control, minimization of dP/dT), it has been shown that many thoracic aortic injuries can undergo delayed repair, perhaps resulting in superior outcomes when compared with those patients undergoing emergent repair [93,94]. A recent prospective, observational study sponsored by the American Association for the Surgery of Trauma (AAST) looked at the subgroup of patients that underwent immediate repair versus those that underwent delayed repair [95]. Those patients that underwent delayed repair of stable thoracic aortic injury actually had improved survival regardless of the presence of major associated injuries, although their length of ICU stay was longer. It should be noted that patients with no major associated injuries who underwent delayed repair had a significantly higher complication rates when compared to those patients undergoing immediate repair. Although there has not been a randomized, controlled trial of early versus delayed repair, these results probably are affected by selection bias. However, selection bias, which reflects the “art” of clinical treatment planning, should not be underscored when making decisions regarding these often multiply injured patients. In addition, successful nonoperative therapy of descending thoracic aortic injury has been reported [96]. Justification for nonoperative therapy includes favorable anatomy of the injury (contained, small injury, hemodynamic stability) as well as the presence of coexisting injuries, which would render the operative risk prohibitively high. These include patients with spinal cord injury that might make lateral decubitus positioning dangerous, patients with pulmonary contusions that may make single lung ventilation difficult, and patients with closed head injury, solid abdominal organ injury, or major fractures in which systemic heparinization would be ill-advised. One accepted method of operative repair is the “clamp-and-sew” technique, in which the proximal and distal aorta are simply clamped, thereby isolating the injury so that either primary repair or interposition grafting can be performed. Operative mortality is generally reported to be 10% to 20% in most series, with major morbidity including renal failure and paraplegia, which appears to increase with prolonged (i.e., >30 minutes) clamp times [97]. Another accepted method of operative repair utilizes bypass of the injured segment during repair, either with partial left heart bypass or with proximal to distal aortic shunt placement (i.e., Gott shunt). Partial left heart bypass (with cannulae in the left atrium and distal aorta) allows controlled off-loading of the left heart in addition to maintaining distal aortic perfusion, especially to the kidneys, that may decrease (but not negate) the incidence of paraplegia, especially when prolonged clamp times are anticipated. Since there has not been a randomized controlled trial comparing the two techniques, and there is no conclusive evidence
that one technique is superior over the other in terms of outcome, both methods are acceptable, and their performance is usually based on surgeon preference.

The need for operative repair, however, which was once considered the gold standard, is now coming into question. There have been many reports showing that “TEVAR” (Thoracic Endovascular Aneurysmal Repair) endovascular stent grafting of selected patients may actually be superior to that of “mandatory” operative repair \([98−100]\). A prospective, multicenter study sponsored by the AAST was recently published that clearly shows the early efficacy and safety of endovascular stent grafting in selected patients with traumatic thoracic aortic injuries \([100]\). The patients who underwent stent grafting had a significantly lower mortality (adjusted odds ratio: 8.42; 95% CI: [2.76 to 25.69]; adjusted \(p\) value <0.001) and fewer blood transfusions (adjusted mean difference: 4.98; 95% CI [0.14 to 9.82]; adjusted \(p\) value <0.046) compared to those patients that underwent operative repair. In addition, among the patients with major extrathoracic injuries, a significantly higher mortality and pneumonia rate were found in the operative group (adjusted \(p\) values 0.04 and 0.03, respectively). The major drawback seen for patients undergoing stent grafting were device-related complications, which developed among 20% of the patients. Their conclusion was that stent grafting of thoracic aortic injuries is now more commonly chosen by surgeons as the preferred method of repair and is associated with significantly lower mortality but that there is a considerable risk of serious device-related complications. The rate of device related complications is continually decreasing in recent literature. Additionally, the rate of paraplegia has ranged between 1% and 3%, significantly less than any open surgical method \([98]\). Also, systemic heparinization, a major risk in trauma patients, is not required. TEVAR has now become the method of choice in many centers for repair of thoracic aortic transection for the high risk or multi-injured patient who would not tolerate open surgery. As more experience is gained, it is conceivable that this method will supplant open surgical repair for all thoracic aortic injuries.

**Traumatic Asphyxia**

Traumatic asphyxia occurs as a result of a sudden or severe compression injury of the thorax or upper abdomen. It is most often associated with blunt trauma secondary to a crush injury. Entrapment of children under
automatic garage doors is a prime example, as reported by Kriel et al. [101]. The true incidence of traumatic asphyxia is unknown, but it is considered to be a relatively rare event. The diagnosis is usually made based on the mechanism of injury and physical examination. Associated injuries are common and therefore should be investigated. The usual physical findings consist of facial edema, cyanosis, and petechial hemorrhages of the upper torso, neck, and face. The petechiae usually occur within the conjunctiva and oral mucosa and become most prominent a few hours after the initial injury. Neurologic findings are not rare and are thought to be secondary to anoxic injury, as well as possible cerebral edema and hemorrhage. The exact pathophysiology is thought to relate to prolonged elevation of central venous pressure (CVP). Prolonged application of high pressure to the mediastinum causes the heart to force blood out of the right atrium retrograde into the valveless innominate and jugular venous system. In addition, a sudden reflexive inspiration is thought to occur against a closed glottis, which may elevate the intrathoracic pressures to high levels. This results in a sudden and rapid increase in the pressure of the small veins of the face and neck, resulting in the typical petechial hemorrhages that are observed.

Treatment is generally supportive. Specific therapy for traumatic asphyxia is based on physiologic techniques to decrease intracranial pressure, including elevation of the head of the bed and oxygen therapy. If there is altered mental status, CT scanning of the head should be done. If there is evidence of increased intracranial pressure, ICP monitoring and treatment of intracranial hypertension may be needed. Laryngeal edema may occur necessitating airway control by endotracheal intubation or emergent cricothyroidotomy. The need to concurrently treat associated injuries is also likely. Commonly associated injuries include rib fractures, pulmonary contusions, extremity fractures, pneumothorax, hemothorax, flail chest, and blunt pelvic and intra-abdominal injuries (i.e., splenic and/or liver lacerations). The prognosis for patients with traumatic asphyxia is generally good, as long as the patient did not sustain prolonged apnea or hypoxia. The majority of fatalities are usually from associated injuries and their complications. When death does occur, it usually occurs in patients who have sustained a prolonged compression, causing massive irreversible neurologic insult from the resultant apnea and hypoxia.

Respiratory Complications

As a result of either primary lung contusion or from the treatment necessary to treat generalized traumatic injury (e.g., massive transfusions, mechanical ventilation, etc.), the lungs are susceptible to acute injury. Complications, which can develop, include transfusion
related lung injury (TRALI), ventilator associated pneumonia (VAP), or ARDS. For an in depth discussion of these three complications, readers are referred to Chapters 89, 163, and 181.
UTILITY OF ULTRASONOGRAPHY FOR EVALUATION OF THORACIC AND CARDIAC TRAUMA

Ultrasonography is valuable for the immediate assessment of the critically ill patient with thoracic and cardiac trauma in the form of the extended FAST examination [102]. Chest CT and angiography are useful for definitive imaging of thoracic and cardiac trauma but cannot be used on an emergency basis. For some applications, ultrasonography is superior to standard supine chest radiography.

The ultrasonography examination is performed by a single member of the trauma team, while other key elements of initial resuscitation are ongoing. Modern bedside ultrasonography machines are small enough that they can be brought to the bedside without blocking access to the patient by other members of the trauma team. The machine has multiple uses beyond examination for life threatening complications of thoracic trauma such as vascular access, airway management, and assessment for alternative causes for shock.

Equipment Requirements

The extended FAST examination is performed using a phased array cardiac probe (2.0 to 5.0 MHz). For the thoracic assessment, the probe is configured with abdominal preset. The machine is switched back to cardiac preset when examining the heart. Many portable ultrasound machines have full TEE capability, so it is feasible to use TEE as an immediate imaging modality at point of care.

Scanning Technique

With the patient in supine position, the operator examines the anterior and lateral chest with the probe held perpendicular to the chest wall and adjusted to scan through the intercostal spaces. A series of scan lines are performed over the anterior and lateral chest, while the probe is moved over adjacent rib interspaces. Generally, it suffices to perform one scan line in the anterior midclavicular line, the anterior axillary line, and the posterior axillary line. In each intercostal space, the operator checks for
Examination for Pneumothorax

The presence of lung sliding, lung pulse, or B lines rules out pneumothorax at the site of the examination (see Chapter 11 Lung Ultrasonography). Multiple intercostal spaces can be examined in a short period time in order to exclude pneumothorax with a high level of certainty in the patient with thoracic trauma. If lung sliding is absent with the presence of A line pattern, there is a high probability of a pneumothorax. Identification of a lung point verifies the presence of pneumothorax (see Chapter 11 Lung Ultrasonography). However, lung point requires a skilled operator. It is highly specific for pneumothorax, but its sensitivity depends on the skill of the examiner [103].

Ultrasonography is similar or superior to standard supine chest radiography for evaluation for pneumothorax [104,105]. Its performance characteristics are such that it may replace chest radiography for this purpose [8]. CT scan remains the gold standard, but, in comparison, ultrasonography gives similar results and offers the advantage of being a point of care technique.

Examination for Hemothorax

Hemothorax is readily detected with ultrasound [106,107]. The hemothorax will accumulate in the dependent thorax, so the examination is focused on the lateral and posterolateral intercostal spaces. A very recent hemothorax has a swirling characteristic and significant echogenicity (see Chapter 12 Thoracentesis). Within a short period of time, blood becomes progressively more hypoechoic. The cellular elements within the blood collection undergo gravitational sedimentation; so it is common to see a clear sedimentation effect with an anechoic space clearly demarcated from a dependent more echoic area. This has been termed “hematocrit” sign. The blood may eventually form a mobile thrombus that is visualized as a distinct structure floating in the anechoic fluid collection. If a hemothorax is present, ultrasonography allows identification of a safe site for chest tube insertion.
Examination for Lung Contusion

Ultrasonography can detect lung contusion related to thoracic trauma. Contused lung appears as B lines or areas of areas of alveolar consolidation, depending on the severity of the injury. It may be focal, multifocal, unilateral, or bilateral in distribution (see Chapter 11 Lung Ultrasonography). The injury may appear rapidly following the trauma and may evolve in severity over time. The finding of B lines and alveolar consolidation is not diagnostic of lung contusion. Their presence is a nonspecific finding indicating lung injury of some type (e.g., aspiration, pneumonia, ARDS); the diagnosis of lung contusion remains a clinical diagnosis that may be supported by the ultrasonography findings. The severity of lung contusion detected by ultrasonography is predictive of the need for mechanical ventilatory support [108].

Examination for Cardiac Injury

The extended FAST examination includes the subcostal long axis view of the heart. This view is designed to detect a pericardial effusion. The finding of a pericardial effusion in the thoracic trauma patient with hemodynamic compromise requires consideration of pericardial tamponade requiring immediate decompression. An acute hemopericardium is relatively echogenic (See Chapter 17 Pericardiocantesis). The operator who is competent at goal directed echocardiography is able to recognize pericardial fluid, but, lacking skill at advanced critical care echocardiography, cannot make more advanced measurements that indicate the presence of tamponade physiology. These are not relevant to the patient who is near death from thoracic trauma with a pericardial effusion. In this situation, the finding of the pericardial effusion is sufficient to take definitive action to drain the fluid either percutaneously or with surgical intervention. Examination for cardiac contusion, valvular injury, and/or penetrating cardiac injury requires training in advanced critical care echocardiography. As goal directed echocardiography is not designed to reliably detect this type of injury, the management team obtains immediate consultative echocardiography, if there is clinical indication to do so.

TEE for Examination for Thoracic Aortic Injury

Transoesophageal echocardiography has utility in identifying thoracic aortic injury [109]. While CT and angiography are standard means to make the diagnosis, TEE has the advantage of immediate feasibility, safety, and utility in identification of thoracic aortic injury. Assuming that the trauma team has TEE capability, it is appropriate to use TEE as the
primary imaging modality and reserve CT scan and angiography for cases where TEE is nondiagnostic or contraindicated. This approach is predicated on immediate availability of TEE to the trauma team and a team member who is competent in the procedure. As critical care echocardiography becomes more widespread, trauma specialists will develop capability with TEE, as the procedure is feasible, has low risk, and has strong clinical utility. However, its use requires an understanding of the limitations of TEE for evaluation of thoracic aortic injury.

1. TEE has contraindications that apply to all patients. Two of these are of special concern in the thoracic trauma patient. An absolute contraindication to TEE is esophageal injury, and cervical spine injury is a relative contraindication.

2. The aortic arch is often difficult to image with TEE due to the presence of the air-filled trachea that may block visualization of this area. The aortic arch includes the take-off of the brachiocephalic, left carotid, and subclavian arteries. Unless the TEE examination is definitive in this area, it may be necessary to proceed with alternative imaging technique such as CT or angiography [110].

3. While TEE has excellent sensitivity for detection of acute thoracic aortic injury, its specificity is reduced due to the problem of intraluminal linear artifacts that are often observed in the ascending aorta and less commonly in the descending aorta. These are classified as multiple-path artifacts that are the result of reverberations between strongly reflective surfaces. When the ultrasound beam strikes an interface with large impedance mismatch between media, multiple reflections occur, especially if the interface is perpendicular to the direction of sound propagation. In the case of the ascending aorta, these commonly occur when the left atrium or right pulmonary artery are smaller in diameter than the ascending aorta. The source of the reverberation artifact is the interface between the posterior wall of the ascending aorta and the anterior wall of the left atrium or right pulmonary artery. Reverberations between this interface and the esophageal transducer may occur with the resultant linear reverberation artifact occurring in the aorta. The resulting linear artifacts do not correspond to anatomic structures, as they derive from reverberation between an interface and the ultrasonography transducer in esophageal position. These linear artifacts may be misidentified as intraluminal dissection flaps and lead to surgical intervention for a false positive result [110]. The trauma specialist who is responsible for the examination has special skill at distinguishing linear artifacts within the thoracic aorta from true aortic dissection, as well as having mastery of the standard components of critical TEE that
include other findings of thoracic trauma: cardiac injury, mediastinal hematoma, and aortic disruption (intimal vs. subadventitial) [111,112]. Table 43.1 and its accompanying reference 110 summarize useful TEE findings that allow the operator to identify linear artifacts within the thoracic aorta.

therapeutic management of patients sustaining blunt aortic injuries. J Trauma 58:1150–1158, 2005.)
SUMMARY

In summary, most thoracic trauma can be managed without surgery or, at most, with minimally invasive interventions. Multiply injured patients with thoracic injuries need to be comprehensively evaluated and their injuries prioritized and as a result, their successful care often requires a multidisciplinary approach. The treatment for thoracic injuries is evolving and requires a working knowledge of a number of both diagnostic and therapeutic modalities. As with almost all other traumatic injuries, the key to optimal treatment and outcomes is dependent upon having a high index of suspicion for the injury and to identify it early. The ability to competently manage all aspects of a critically injured patient is also important in effecting a successful overall outcome.

endovascular stent graft in blunt traumatic thoracic aortic injuries:

Chapter 44

Critical Care of the Patient with Abdominal Trauma
JON D. DORFMAN

The success of nonoperative treatments and the ubiquitous availability of high-resolution CT scans have changed the management and possible complications from traumatic injuries. This chapter will focus on complications of abdominal trauma that an intensivist should recognize.

One possible origin of the word abdomen is the Latin *abdere*, meaning to conceal. Few areas of the human body are as difficult to assess following injury or to monitor subsequently as is the abdomen, particularly in the obtunded or intubated patient. Much of the morbidity and mortality due to abdominal injury results from delay in recognizing conditions that can be corrected once identified. Once the patient is admitted to the intensive care unit (ICU), the ability to follow changes occurring within the abdomen deteriorates.

ICU ADMISSION

In previous years, trauma patients arriving in the ICU were assumed to have had their injuries identified and definitively treated, frequently in the operating room. Today, the ICU plays a different role in the care of blunt trauma patients, commonly continuing the initial resuscitation to specified endpoints to allow the patient to return to the operating room for definitive care. In the majority of blunt trauma patients, who frequently are managed nonoperatively, the ICU must carefully follow the patients for signs of bleeding or failure of nonoperative management and monitor for the potential complications of “missed” injuries. In patients, who do have operations, they may undergo “damage control” surgery; these patients have staged operations with resuscitation in the ICU between operations. Furthermore, the resuscitation for traumatic abdominal injuries is now known to have systemic physiologic effects.
Trauma surgeons have traditionally separated injured patients into those injured by blunt mechanisms such as car crashes and falls and those injured by penetrating mechanisms, which are subdivided into gunshot wounds or stabbings. Blunt trauma patients are more frequently managed nonoperatively, whereas penetrating trauma, particularly gunshot wounds, more often require operative exploration.

Operative trauma patients will have had a laparotomy, and their injuries should have been defined. However, there still exists a rate of missed injuries of up to 10% [1]. There will be a tendency for the intensivist to consider these patients identical to the elective general surgical patient who has undergone a comparable operation. Although there are certainly areas of commonality, there are critical differences that must be considered. The general surgical patient will usually have only a single acute problem unlike the trauma patient who may have sustained injuries to multiple body regions and possibly more than one organ in the abdomen. These differences often lead to management problems and complications that would not be expected of the general surgical patient.

Many blunt injury patients and selective penetrating injury patients are now managed with the intention of not operating on them. This approach has grown out of the recognition that many trauma laparotomies are nontherapeutic as opposed to negative. For example, a laparotomy for hemoperitoneum that identifies a small liver laceration and a minor tear in the mesentery is certainly not a “negative” laparotomy, but if both injuries have stopped bleeding spontaneously, it is difficult to argue that the surgery was therapeutic. Nontherapeutic laparotomies are not without consequences. Operations are painful; they expose the patient to complications rates in older series of up to 41% [2] and in more recent studies of 14% [3]. Complications include wound infections, pneumonia, urinary tract infections, deep venous thrombosis as well as ileus, bowel obstruction, and incisional hernias. Thus, the risks and benefits of operating must be balanced by trauma surgeons.
NONOPERATIVE MANAGEMENT

Nonoperative management of intra-abdominal injury is so widely practiced that trauma surgeons often feel they have to attempt nonoperative management or justify why they want to operate on a splenic or liver laceration. Nonoperative management of abdominal solid organ injury is appropriate only for hemodynamically stable patients whose injuries are identified by imaging. Hemodynamic stability is not as easy to define as it would appear. Advance Trauma Life Support for Doctors defines hypotension as a systolic blood pressure of 90 mm Hg. However, there are exceptions to this rule. The elderly, in particular, have an increase in mortality with blood pressures lower that 110 to 120 mm Hg [4]. Certainly, patients who require ongoing resuscitation with blood and blood products or pressors to maintain normotension are not considered stable. Other factors to consider include tachycardia or metabolic acidosis, and if present, would also preclude a state of physiologic stability. Additional factors should be considered before a decision to attempt nonoperative management is made. Are there medical conditions such as portal hypertension or the use of anticoagulants? Patients with severe head injuries or ischemic heart disease are often considered to be at high operative risk, but a failure of nonoperative management also poses a high risk of mortality [5,6].

As imaging has improved, trauma surgeons have been given a more precise determination of the anatomic location and severity of the injury prior to deciding whether or not an operation is indicated. This information has allowed the construction of a number of models intended to predict the success of nonoperative management [7]. CT-based injury grading systems have been shown to correlate with clinical outcomes, but, as with most scoring systems, work better for analyzing populations than for predicting the outcome of an individual patient [8,9].

One of the most useful CT findings is the presence of extravasated vascular contrast. This contrast blush usually represents either active bleeding or a pseudoaneurysm of a parenchymal artery. Such patients have a higher probability of failing nonoperative management. Angiographic embolization of the injured vessel may help to restore them to the nonoperative pathway [10].
Spleen

The current practice of managing splenic injury nonoperatively comes from recognition of the immunologic importance of the spleen and the risk of overwhelming postsplenectomy sepsis. Furthermore, realization grew that many splenic injuries required no intervention. The practice of nonoperative management began in pediatrics and has gradually extended into the adult population, for whom nonoperative management is not as successful. Nonoperative failure rates range from 2% to 13% [11]. Predictors of failure of nonoperative management include grade of injury [12], active contrast extravasation, and in some studies, age over 55 years old [13]. Isolated lower grade injuries are unlikely to be admitted to the ICU as the risk of failure of nonoperative management and the risk of mortality are low. If low grade injury patients are admitted to the ICU, it is most likely due to concomitant injuries or significant patient comorbidities. The intensivist should remember that even low grade injuries have a small chance of bleeding that would require intervention. For injuries grade III and higher, the rate of failure of nonoperative management increases and is particularly significant in grade IV (60%) and grade V (75%) injuries [14].

Nonoperative management fails in up to 15% of all patients with splenic injury. In prior studies, 75% of these failures occur within 2 days, and almost 95% of the failures occurred within one week [13].

The nonoperative management of a ruptured spleen must be a joint effort between the surgical and the ICU teams. Parameters that change the management strategy should be agreed upon in advance. In general, any sign of ongoing hemorrhage should lead to immediate surgery and splenectomy. If the patient experiences a steadily falling hemoglobin level but never manifests any change in vital signs, there should be prior agreement regarding the number of units of packed red blood cells (PRBCs) to be transfused before intervening. The absolute number will vary with the estimated operative risk, and other factors predicting success or failure.

Splenectomy may be an option in some facilities for those patients whose CT demonstrates a contrast blush within the spleen. Patients admitted to the ICU for nonoperative management of a higher grade (III to IV) isolated splenic injury should receive their planned immunizations, including pneumococcal, meningococcal, and Hemophilus influenza vaccine, since there is evidence that these vaccines are more effective with the spleen in situ [15].
Other elements of the patient’s care are determined in conjunction with the trauma surgeon, or institution. Many centers have protocols that determine the frequency of hemoglobin blood draws, the advancement of activity, when to change the diet, and when to start venothromboembolism (VTE) chemoprophylaxis. Although many studies have been performed, the data have not been conclusive enough to guide the institution of these measures [16]. Most centers start VTE prophylaxis within 48 hours of injury, assuming hemodynamic stability and significant bleeding has ceased.

Another major complication is an infection involving the injured splenic parenchyma or the perisplenic hematoma resulting in either splenic or subphrenic abscess [17]. Unexplained fever, leukocytosis, or pleural effusion should lead to consideration for an abdominal CT scan looking for evidence of infection. Most infections can be effectively treated with antibiotics and percutaneous drainage, but failure to respond promptly should result in exploration, evacuation of the infected hematoma, and splenectomy.

Liver

The other commonly injured abdominal organ from blunt trauma is the liver. As in splenic injuries, nonoperative management of liver injuries has a high success rate (>80%). Although the surgical options differ from the spleen, the decision to operate should be based on similar considerations. The first criterion for successful nonoperative management is hemodynamic stability. A patient who does not meet this condition should be taken to the operating room and explored; surgically, the options include cauterization and placement of sutures. Formal liver resection has a high mortality rate. Treatment can be also be staged with placement of perihepatic packing with or without interventional radiology angiography and embolization with later reexploration after resuscitation, or transfer to a center with additional capabilities.

Patients who remain normotensive or who are successfully resuscitated in the trauma bay will likely have had a CT scan with intravenous contrast. In prior studies, contrast extravasation into the peritoneum on CT scan is likely to require an intervention (operative or angiographic), because these patients are likely to become hemodynamically unstable [18]. Contrast blush or high grade injury may be considered an indication for angiogembolization. Angioembolization is not without risks. Risks include hepatic necrosis requiring surgical debridment and, more
commonly, gallbladder ischemia requiring cholecystectomy [19,20]. Liver injuries in the setting of cirrhosis, portal hypertension, or coagulopathy are much more likely to fail nonoperative management than comparable injured patients lacking these comorbidities.

Complications of nonoperative management include intraperitoneal hemorrhage, hemobilia, bile leak or biloma, biliary ascites, hepatic necrosis, and abdominal compartment syndrome [21]. Higher grades of liver injury are associated with higher rates of complications. Delayed bleeding from a liver laceration is uncommon, and if it were to happen, usually occurs within 24 hours postinjury.

Biliary complications occur later than delayed bleeding. Rising liver function tests, fevers, tachycardia, and worsening abdominal pain are an indication for repeat CT scan, or hepatobiliary iminodiacetic acid (HIDA) scan to evaluate for a bile leak. Management of biliary complications include percutaneous drainage of symptomatic bilomas, endoscopic retrograde cholangiopancreatography with biliary stenting, and laparoscopy or laparotomy. Frequently, multimodality treatment is necessary.

Hemobilia is an uncommon complication. Most cases are associated with penetrating rather than blunt hepatic trauma. The classic triad of gastrointestinal hemorrhage, jaundice, and right upper quadrant pain may suggest the diagnosis, although all three signs and symptoms are infrequently present. It may occur within days of the injury to years later. Diagnosis is often difficult and delayed. The bleeding may be intermittent so that diagnostic endoscopy may demonstrate no source for the bleeding. Hepatic angiogram and embolization is considered the first-line therapy, although rarely operative intervention is required [22].

**Kidney**

Renal injury is most often the result of blunt trauma and rarely occurs in isolation. Right renal injury most frequently occurs in conjunction with hepatic injury, and left renal injury in conjunction with splenic injury. Renal injury management is usually determined by hemodynamic status. Hemodynamic instability due to a renal injury, typically a high grade renovascular injury (Grade V on the American College of Surgeons Scale of I to V), usually results in nephrectomy. The literature on attempting surgical repair shows that this is usually unsuccessful but should be considered if the trauma patient had only a single functional kidney to begin with [23]. However, in hemodynamically stable high grade IV and V injuries, nonoperative management is still possible and highly successful [24].

The complications of renal injury include hemorrhage and urine leak. Hemorrhage can present as hematuria, but the severity of the hematuria
and the degree of the renal injury are often discordant. Gross hematuria may appear dramatic, but most renal bleeding diminishes spontaneously. In some persistent cases, angioembolization may be necessary. Microscopic hematuria is common after blunt abdominal trauma and is of little consequence. Hemorrhage requiring an operation can occur up to 4 days postinjury in some series [24].

Urine leak from an injured kidney can also occur but may resolve spontaneously. Extravasated contrast that is confined within Gerota’s fascia does not mandate intervention. Leakage of urine as demonstrated by delayed contrast extravasation outside of Gerota’s fascia may still resolve but is more likely to require intervention. Persistent urine leakage or urinoma may need treatment, which can include a combination of ureteral stents, a nephrostomy tube, or percutaneous drainage.

Pancreas

Blunt pancreatic injury is typically the result of high-energy impact to the epigastrium from such mechanisms as handle bar injury in bicyclists or steering wheel injury in a motor vehicle crash. Physical findings are usually minimal. Pancreatic injury rarely occurs by itself and is usually associated with injury to adjacent organs or structures such as the liver, kidneys, or spleen. Injury to these organs should heighten your vigilance. The challenge in detection is that laboratory and imaging studies are often nondiagnostic. Mortality rates of up to 40% are reported from high grade injuries. Injury to the pancreas is one of the classic “missed injuries” that may not become apparent until days later.

Serum amylase and lipase may be monitored after blunt abdominal trauma. Amylasemia is not specific to pancreatic injuries, and therefore the sensitivity and specificity is low. For example, traumatic brain injury and salivary gland injury can lead to a rise in amylase levels. Lipase is also not predictive of injury. Furthermore, serum amylase drawn within 3 hours of the injury is inaccurate. Finally, the extent of amylasemia elevation does not correlate with extent of injury [25].

Imaging of the pancreas also has limitations. Abdominal CT scans with intravenous contrast are commonly performed and are normal in up to 40% of patients with a pancreatic injury. The findings may be nonspecific and may not appear for 12 hours or more after injury. These findings include signs of inflammation or “stranding” around the pancreas. Other signs may include lacerations, contusions, or hematoma.

The critical factor that determines the management strategy of pancreatic injuries is whether or not the main pancreatic duct is injured. AAST low grade injuries (I and II) do not involve the duct, whereas high grade injuries (III to V) have main ductal injury. If pancreatic ductal disruption is present, distal resection or internal drainage produces much
less morbidity than simple drainage or noninvasive management [26]. If no definitive reason for surgical exploration exists but there is reason to suspect or diagnose a pancreatic injury, it is imperative to evaluate the ductal integrity. If there is any suggestion of instability or peritoneal signs, this should be performed at the time of abdominal exploration. Otherwise, the patient may be a candidate for magnetic resonance cholangiopancreatography (MRCP) or ERCP. Delay in diagnosing and providing definitive therapy for a ductal injury may have devastating consequences.

Pelvic Fracture

Pelvic fractures may be the result of low-energy falls in the osteoporotic elderly or high-energy trauma in a young motorcyclist. In each case, pelvic fractures can lead to life-threatening hemorrhage and complications. There are multiple classification systems for pelvic fractures. One of the more commonly used systems is Young and Burgess, which classifies the fracture on the basis of four impact patterns—anterior posterior compression (APC), lateral compression (LC), vertical shear, and complex—for pelvic fractures that do not fit simply into one of the previous categories. APC and LC have 3 subtypes. The Young and Burgess system aids in understanding the stability of the fracture and the potential complications.

Hemorrhage can be significant; the source of the hemorrhage and hypotension may not initially be certain given the association of pelvic fractures with intra-abdominal solid organ injuries and long bone fractures. Other sources of bleeding must be considered, identified, and dealt with accordingly. Pelvic fracture–associated bleeding can be from injured pelvic arteries, disrupted veins, particularly of the sacral plexus, and even the fractured pelvic bones themselves. The fracture pattern has some association with potential blood loss; APC2 and APC3 fractures as well as LC3 and vertical shear are higher blood loss fracture patterns; APC3 fractures can require 10 units or more of PRBCs for resuscitation [27]. Management options include closing the pelvic ring in APC2 and APC3 fracture patients who are hemodynamically unstable. Wrapping the pelvis at the greater trochanters can achieve temporary closure of the pelvic ring and effectively reduce the pelvic volume. External fixation by orthopedic surgery can be performed in the operating room. Embolization of arterial extravasation is also an option; however, not all patients who have active extravasation on CT scan necessarily require
embolization. Hemodynamic instability and ongoing blood transfusion requirements due to a pelvic fracture are indications for angiography [28]. Performing embolization, however, is not without potential complications. Gluteal muscle and skin necrosis have been reported along with soft tissue infection requiring debridement [29]. For uncontrolled venous hemorrhage, prepelvic packing is advocated at some trauma centers [30]. Even with this armamentarium, the mortality rate from pelvic injury can be quite high.

With large retroperitoneal hematomas, abdominal distension can lead to abdominal compartment syndrome. Ventilation, in particular, can be impaired as the abdominal contents reduce the thoracic volume. Respiratory failure leading to intubation can occur.

Associated injuries with pelvic fracture include long bone fractures and intra-abdominal injury. Intra-abdominal solid and hollow viscous organ injury will be addressed separately. Here it is important to discuss genitourinary and rectal injury, which are more commonly associated with “open book” fractures, APC2 and APC3. Urethral injuries are relatively uncommon (2%). Men are more likely to sustain a urethral injury than women. Suspicion for this injury should be elevated if blood is noted at the urethral meatus or there is a high-riding prostate on rectal examination. A retrograde urethrogram can confirm the injury; if found, this injury is treated with placement of a urinary catheter or temporized with a suprapubic tube. Bladder injury can occur as well and should be considered if gross hematuria is noted. CT cystogram can confirm the diagnosis and determine whether the injury to the bladder leads to intraperitoneal or extraperitoneal urine leakage. Intraperitoneal leakage requires operative repair via a laparotomy and with prolonged bladder decompression with a urinary catheter. Extraperitoneal leakage may be managed with only a urinary catheter for 2 weeks [31]. Rectal injury should also be considered for all pelvic fractures but is most commonly associated with APC2 and APC3. Blood on rectal examination should prompt rigid sigmoidoscopy and consideration for diverting colostomy. Untreated rectal injuries may lead to abscess formation and pelvic sepsis.

Other

Nonoperative management of abdominal injuries is the treatment strategy for the solid organs, including the liver and spleen, as previously discussed. Hollow viscous injuries are usually managed with an intervention except in two particular circumstances. These two exceptions are intramural hematoma of the duodenum and extraperitoneal rupture of the bladder.

Blunt duodenal injuries are primarily the result of a blunt force to the epigastrium such as from the steering wheel or seat belt in a motor
vehicle crash and handle bars in a bicycle crash. In the AAST grading system, duodenal hematomas are either Grade I or II injuries, depending on the length of the duodenum involved [32]. Symptoms, when present, will usually be those of gastric outlet obstruction. Diagnosis is made from a CT scan with oral contrast or an upper gastrointestinal study. The patient should be carefully evaluated for any evidence of a concomitant pancreatic injury. If there are no associated injuries, nonoperative management is recommended. Gastric decompression with a nasogastric tube and nutritional support with total parenteral nutrition should be prescribed. Periodic radiographic reevaluation should occur to determine whether the obstruction has resolved. If it has not resolved within several weeks, evaluation for possible stricture should be considered.

Approximately 80% of bladder injuries occur in the setting of pelvic fracture, although only about 5% of pelvic fractures are associated with bladder injuries [33]. Bladder injuries are often extraperitoneal and result from perforation of the bladder by bone fragments from fractures of the parasymphysis of the pelvis. This may occur even though the final position of the bone fragments as demonstrated on radiographs does not appear near the bladder. Bladder injury is also suggested by the inability to void, incomplete return of catheter irrigation into the bladder, and gross hematuria. Any pelvic fracture associated with gross hematuria requires a cystogram. Diagnosis requires retrograde contrast injection into the bladder with images taken in both the anteroposterior (AP) and lateral views and postvoiding. CT scan with contrast can also give a high-quality image of the bladder by clamping the Foley catheter to distend the bladder. Extraperitoneal injuries typically will heal with bladder decompression by a urinary catheter for 7 to 14 days. Prior to removal of the catheter, a repeat cystogram should be obtained to confirm resolution of the injury. Persistent extravasation may require surgical repair of the bladder.
PENETRATING INJURY

In some institutions, patients with penetrating trauma may be selected for nonoperative management and admitted to the ICU for close monitoring. As with blunt trauma, the fundamental requirement for nonoperative management is hemodynamic stability and the absence of peritonitis. Any hemodynamic instability or the development of peritoneal signs mandates exploration.

Stab wounds are much more likely to be monitored nonoperatively than gunshot wounds. This type of penetrating abdominal injury has a lower incidence of penetrating the posterior abdominal fascia, and even if penetration occurs, only a fraction of stabbings cause an injury that requires repair. The ICU team will monitor for hemodynamic changes, a change in abdominal examination, and signs of abdominal sepsis [34].

Gunshot wounds are infrequently managed nonoperatively if the bullet enters the peritoneal cavity because of the higher probability of visceral, particularly hollow viscus, injury. However, CT imaging is now allowing the nonoperative management of highly selected abdominal gunshot wounds. These cases are primarily patients who are hemodynamically stable, have no peritoneal signs on examination, or for whom the entire tract of the missile appears to lie within a solid organ (liver, spleen, kidney, retroperitoneum). Such patients should be monitored in a manner similar to blunt trauma patients with the exception that hollow viscus injury is still a concern [35].
MISSED INJURIES

Missed injuries may be a misnomer because the injury may not have been apparent or detectable at the time of arrival at the hospital. Furthermore, no matter how careful the initial evaluation of the trauma patient, almost all series report an approximately 10% incidence of missed injuries that are discovered in a delayed fashion [36]. Most of these are minor extremity fractures discovered as the patient begins to increase activity and reports pain. The delay in diagnosis is generally inconsequential. However, a delay of the diagnosis of a hollow viscus injury may have serious consequences. Avoiding delays in diagnosis requires the cooperation of the entire team providing care to the patient. The initial assessment should be thorough and take into account the mechanism of injury, external signs of trauma, patient complaints, and laboratory and radiographic findings. In spite of such a detailed and comprehensive evaluation, additional information will often become available over the first 24 to 48 hours. Bruises, abrasions, seat belt marks, will often be more apparent the next day. Laboratory and even imaging studies are less sensitive when the patient arrives at the trauma center within a few hours of injury. These facts have led many trauma centers to institute a formal tertiary survey within 24 hours of admission [37]. During the tertiary survey, the patient should be carefully reexamined from head to toe for new evidence of traumatic injury. Radiographs should be reexamined and compared with the now dictated radiology interpretation. Tertiary surveys are even more important when the patient is initially unstable, and examiners may be distracted by the urgency of the situation. Furthermore, patients who had altered mental status from traumatic brain injury or intoxication may now relay new symptoms. Patients who were intubated and unable to communicate may provide important subjective complaints once extubated. Repeat focused assessment sonography in trauma (FAST) or computed tomography (CT) scan should be considered if there is any change in status. Injuries such as pancreatic, or small bowel injuries may be more apparent on a CT scan performed at 24 hours postinjury than on the initial scan.

Bowel

One of the major concerns is the possibility of a missed bowel injury. Direct bowel rupture from blunt trauma is uncommon. Typically, injury occurs to the mesentery, and therefore the blood supply to a segment of small intestine is compromised. The segment of intestine supplied by injured mesentery becomes ischemic over time and may then become
necrotic. A patient who has a bowel injury will likely not have peritoneal signs initially. Peritoneal signs develop over time but may not be apparent in a patient who has a traumatic brain injury, intoxication, intubated on sedation, or has a distracting injury. On examination, a “seat belt” sign or abdominal wall injury from the seat belt has been associated with blunt bowel injury and should increase the index of suspicion.

Injuries can also be missed at the time of surgical exploration. Although the mesenteric injury to the small intestine may be apparent, the retroperitoneal colon injury from a seat belt would not be obvious in the operating room. The intensive care team must be cognizant of the possibility of missed injury and have a heightened vigilance for the signs and symptoms in patients who are not progressing or improving as would be expected. Patients arriving with “negative” abdominal CT scans and the patient admitted following abdominal exploration must be reevaluated for bowel injury if they show signs of unexplained sepsis, prolonged ileus, rising white blood cell (WBC) count, or failure to clear their acidosis.

Patients admitted to the ICU for planned nonoperative management are at particular risk. The sensitivity and specificity of CT scanning is low for hollow viscus injury [38]. Trauma CT scan protocols use intravenous contrast without oral contrast. Even with oral contrast, the free leak of oral contrast into the peritoneal cavity is a relatively infrequent finding. Free air may be demonstrated, but its absence certainly cannot exclude bowel injury. An area of localized thickening of the bowel wall is suggestive of injury, whereas a diffuse thickening is more compatible with either excess fluid administration or poor perfusion. CT findings that cause concern are intraperitoneal hemorrhage without evidence of a solid organ injury to account for the bleeding and signs of mesenteric injury. There is a debate about how much free fluid (hemorrhage) is enough to create concern for bowel injury. Some consider this sufficient evidence for exploration, whereas others disagree [39]. Recent studies attempted to devise scoring systems based on CT imaging, physical examination, and laboratory findings; however, nearly 16% of patients still required a delayed laparotomy [40].

Any mesenteric injury that is not explored surgically must be monitored carefully in the postinjury period to allow the recognition of ischemic bowel prior to perforation. Even with penetrating trauma, there is a missed injury rate. Urgency of hemorrhage control may lead to oversight. An apparently straight missile tract may not have been so straight. Bowel may have been in a different configuration at the time of penetration. Tangential injuries to the intestine on the mesenteric border that appeared not to have injured the intestine are a classic location of missed injury. Areas of bowel injury that did not appear transmural may
have been deeper than was realized. Areas that did not appear injured such as the retroperitoneum may not have been explored. It is incumbent on the operating surgeon to explore the abdomen thoroughly, but in spite of this, injuries will at times be missed. Neither the operating surgeon nor the intensivist caring for the patient in the ICU should dismiss the possibility if the patient is not recovering as anticipated.

Pancreas

Signs and symptoms of pancreatic injury may not manifest immediately. As previously explained, serum amylase and serum lipase will not be elevated if checked within 3 hours of the injury. CT scan findings may be minimal or completely lacking within 12 to 24 hours of the injury. Fluid collections (pseudocysts), pancreatic ascites, pancreatitis, and sepsis may develop days after the injury.

Renal Collecting System

Injuries to the renal collecting system, including the renal pelvis, ureters, and bladder, may present as a rising blood urea nitrogen (BUN) without obvious explanation, as new onset nonhemorrhagic ascites without evidence of cirrhosis, as drainage of serosanguineous fluid from the incision, or as a mass in the flank or pelvis. The diagnosis is usually not difficult as long as a urine leak is considered. CT with intravenous contrast with appropriately timed delayed images will usually establish the diagnosis. Any unexplained fluid collection in the abdomen that is aspirated should be analyzed for creatinine and compared to the serum level. Most injuries that are diagnosed late can be managed with decompression or stenting, although complete transection of a ureter will require operative repair.

Solid Organs

The probability of missing a solid organ injury if the patient has received a CT scan with intravenous contrast is low. CT scans with intravenous contrast identify approximately 98% of solid organ injuries. The probability of missing a significant solid organ injury is even lower. However, solid organ injuries can be missed if the patient does not receive a CT scan on the basis of what is perceived to be a normal physical examination with a false negative FAST examination. As previously discussed, many reasons exist for an erroneous physical examination. Blood in the peritoneal cavity may not cause peritoneal irritation immediately. Intoxication, traumatic brain injury, or distracting injuries can alter the abdominal examination. FAST examinations are intended to assess the presence or absence of free fluid in the abdomen, not injury to
solid organs. Some liver, spleen, or kidney lacerations produce little or no free fluid on initial examination. Patients admitted to the ICU without abdominal CT scanning or with a noncontrast CT should be monitored closely. Any unexplained deterioration in vital signs or change in hemoglobin should prompt an immediate FAST examination or a CT scan if the patient is sufficiently stable to be transported to radiology.
ABDOMINAL COMPARTMENT SYNDROME

Abdominal compartment syndrome (ACS) is a recognized complication of traumatic injury and resuscitation, but the diagnosis may be delayed or missed all together. Recognition of ACS began in the 1800s with reports of the deleterious results of intra-abdominal hypertension, but the clinical diagnosis was imprecise, unreliable, and infrequently made. With the publication by Kron et al. [41] of the indirect measurement of intra-abdominal pressure (IAP) by bladder pressure, diagnosis of ACS became feasible and quantifiable. ACS assumed even greater importance with the widespread use of damage control surgical resuscitation as patients at high risk for ACS should be considered for staged closure. A complete review of ACS is presented in its own chapter 52, including current definitions, pathophysiology, systemic consequences, measuring techniques, and management. We discuss it briefly here as it relates specifically to abdominal trauma.

Pathophysiology

The fundamental physiology of ACS does not differ from any other compartment syndrome. It may occur as a result of bleeding, edema, or packing within the abdomen, referred to as primary compartment syndrome, or as a result of ischemia-reperfusion and capillary leak associated with other disease processes such as major burns or systemic sepsis. This is referred to as secondary compartment syndrome. Pressure within the abdominal compartment increases until the perfusion pressure is inadequate to meet the oxygen and nutrient needs of the tissues within the abdomen or extra-abdominal organ failure results.

As IAP increases, the abdomen distends until it can expand no further. The increased intra-abdominal pressure is transmitted to the surrounding structures. Although the most direct technique involves the insertion of catheter directly into the peritoneal cavity, this is not practical or necessary for injured patients. The accepted clinical technique is an indirect assessment by the bladder pressure measurement.

When IAP rises to a critical level, not only does it compromise blood flow to intra-abdominal organs, it also negatively impacts the respiratory, cardiovascular, and central nervous systems. ACS is defined as an abdominal pressure of more than 20 mm Hg with one or more organs showing signs of dysfunction [42].

Clinical Manifestations
Increases in IAP impact virtually every organ system. Often, the first measurable finding involves the respiratory system, where increased IAP is often the cause of hypercarbia due to decreased minute ventilation. In a pressure control mode, the tidal volumes will decrease. In a volume control setting, peak inspiratory pressures will rise. These changes may be subtle initially, but then dramatic changes will occur rapidly [43,44]. Other possible causes are frequently considered first, such as pulmonary edema and acute lung injury; however, ACS should not be forgotten on the differential diagnosis, or it will be missed and the consequences will be dire.

Increased IAP increases renal vein pressure with elevations in plasma renin and aldosterone as well as decreased renal blood flow, glomerular filtration, and urine output [45]. The result is oliguria and then anuria. In the midst of a trauma resuscitation, oliguria could easily be misinterpreted as hypovolemia and the need for additional resuscitation, which could exacerbate the problem.

The increase in IAP results in an elevated central venous pressure and pulmonary capillary wedge pressure. In spite of this, actual venous return declines, leading to decreased cardiac output and increased systemic and pulmonary vascular resistance. This compromise in venous return is transmitted to the central nervous system, resulting in increased intracranial pressure and decreased cerebral perfusion pressure.

**Management of Intra-Abdominal Hypertension**

In patients judged to be at high risk for the development of ACS, the risk may be reduced by leaving the abdomen open at the time of surgery. Similarly, a patient whose abdominal wall is difficult to close because of edematous bowel or a large retroperitoneal hematoma may be better managed as an open abdomen from the beginning. Anytime there is a suspicion of ACS, the initial diagnostic step should be the measurement of IAP. If IAP is elevated, the therapeutic choices are to either reduce the volume of the abdominal contents by removing space occupying lesions or to enlarge the abdominal compartment. Bedside ultrasound allows the determination of whether there is a significant quantity of free fluid in the abdomen. If so, either a paracentesis or the insertion of a drain may remove enough simple fluid to reduce the abdominal pressure. Large quantities of fluid or gas within distended bowel loops may be removed with a nasogastric tube. IAP may also be reduced in some patients with the use of improved analgesia and even neuromuscular blockade. Although these few special cases should not be overlooked, many cases of ACS will require surgical decompression with some form of temporary abdominal closure.
Open Abdomen

Patients whose abdomen is opened to prevent or treat ACS will require some alternative method of closure to prevent evisceration, to manage fluid loss, and to prevent loss of domain of the abdominal viscera. One of the simplest forms of temporary abdominal wall closure that allows expansion of the abdominal cavity is the towel clip closure. This technique is based on the rapid closure of the skin only with multiple surgical towel clips [46]. Although it is inexpensive and fast, towel clip closure has largely been abandoned in recent years because it has been recognized that a significant number of patients developed a recurrent compartment syndrome. Other methods of temporary closure that allow expansion of the abdominal cavity include placing absorbable mesh or gauze packing [47]. Additional techniques have been based on the silo idea similar to that used for newborns with gastroschisis [46]. Several materials have been utilized for the silo, from 3 L bags of fluid to adhesive drapes to sterile silastic sheets.

Currently, the most popular management of the open abdomen is negative pressure wound therapy [48]. The fundamental principle is the application of a nonadherent barrier over the bowel, followed by negative pressure connection, and then a closed, sealed covering over the abdomen. The benefits of such a negative pressure dressing include reduced wound care, removal of fluid from the peritoneal cavity, and the collapse of any free space in the abdomen. The negative pressure may also minimize the retraction of the abdominal wall muscles. A number of homemade devices have been described, and several commercial systems are now also available.

Once the patient has been resuscitated and abdominal injuries addressed, the next priority is abdominal closure. The longer the abdomen remains open, the greater will be the difficulty in achieving closure as well as the greater the risk of enteroatmospheric fistula formation. To achieve closure of the abdominal wall will require coordination between the surgical and ICU teams, the patient should have a negative fluid balance, and diuretics should be administered as needed. Reapproximation of the midline fascia may require the use of pharmacologic muscle relaxants, multiple trips to the operating room to partially close the abdominal wall each time, or more complex surgical techniques such as component separation [49]. In some cases, fascial closure cannot be obtained, and coverage by closing skin only or placement of a split thickness will be required. This method is not ideal
because it will lead to a ventral hernia that will require repair months to years later once the patient has recovered.

Prolonged exposure of the bowel by any of these techniques results in a substantial risk of enteroatmospheric fistula formation. Fistula formation greatly complicates the wound management as well as fluid and nutritional management. The primary goal of this phase of open abdominal management is to achieve some form of wound closure before enteroatmospheric fistula formation occurs.
DAMAGE CONTROL RESUSCITATION

Damage Control Surgery

Historically, trauma surgeons attempted a single definitive operation. In patients with large injury burdens or serious physiologic derangements, recognition of the benefits of staging the operation has occurred. In these carefully selected patients, hemorrhage control and then control of enteric spillage is prioritized. The reconstruction to obtain gastrointestinal continuity and closure of the abdominal wall is left to later procedures once the patient’s physiologic condition improves. This damage control philosophy attempts to abort the cycle of the “triad of death” [50] in which hypothermia, acidosis, and coagulopathy worsen until the patient expires. This technique has become widely used and applied for traumatic and nontraumatic abdominal catastrophes. Damage control has been advocated in the following circumstances: if more than 10 units of blood has been transfused, base excess of −18 mmol per L or less if patient is less than 55 years old; base excess of −8 mmol per L or less if patient is greater than 55 years old; lactic acidosis greater than 5 mmol per L; hypothermia of less than 35°C [51]. Damage control surgery, as generally practiced, consists of three phases:

I. Limited operative intervention aimed at controlling hemorrhage, usually by ligation, shunting, or packing, and at controlling contamination, usually by ligation or stapling. Little or no repair or reconstruction is performed at this stage. Abdominal closure is rapid and temporary.

II. Resuscitation in the ICU to correct hypovolemia with blood products, hypothermia by active warming, and coagulopathy by replacement of coagulation factors.

III. Planned return to the operating room to look for additional injuries, perform definite surgical procedure, remove packs, and to close the abdominal wall. This phase should take place only when the physiologic derrangements described above have been corrected.

Inability to resuscitate the patient and correct the physiologic deficits of acidosis, hypovolemia, hypothermia, and coagulopathy may reflect continued bleeding or an injury that needs to be addressed. It is not difficult to overlook a surgical bleeding site when it is obscured by diffuse nonsurgical bleeding. Furthermore, vessels may spasm and once hypotension is corrected in the ICU, may hemorrhage again. Making the
decision to return to the OR before correction of the deficits is a difficult one. Various criteria have been described for emergent return to the OR [52], but in practice, the decision is often based on progress or the lack thereof. If the temperature, the pH, the coagulation studies, and the vital signs are getting better, it is usually worth continuing with resuscitation in the ICU. If there are signs of ongoing bleeding and physiologic parameters are worsening, it may be worth the risk of transporting the patient back to the OR for another look or considering angioembolization if the surgical team feels that an operative intervention will not be of benefit, for example, a liver injury that has been packed already.

**Acidosis**

Hypovolemic shock of the severely injured patient produces a metabolic derangement that will not have disappeared with the restoration of normal vital signs. One manifestation of this metabolic failure is a lactic acidosis. A variety of endpoints for resuscitation have been proposed, but none have been shown to be more reliable than resolution of the lactic acidosis. The role of crystalloid as a resuscitative fluid has changed over the past decades. Intravenous fluid is acidotic, and only a fraction remains intravascular. Crystalloid causes cellular swelling, organ edema, and dysfunction and is proinflammatory [53]. The resuscitative volume expander of choice in patients with hemorrhagic shock has become blood and blood products with limited crystalloid administration. Recent data suggest that more of the resuscitation should be based on blood and blood products with lower ratios with a proven benefit to patient outcomes [54,55].

Severe acidosis increases the risk of cardiac arrhythmias, reduces the effectiveness of endogenous and exogenous catecholamines, and worsens coagulopathy. The enzymes of the coagulation cascade do not function as well in pH ranges outside of homeostasis; furthermore, platelet dysfunction occurs. Thus, it may be appropriate to use alkalinizing agents such as sodium bicarbonate or THAM (trishydroxymethylaminomethane) to raise the pH above 7.2 [56]. There is no clinical proof of mortality benefit, however, from this practice of correcting the acidosis with alkalinizing agents.

**Hypothermia**

Hypothermia and traumatic injury are a lethal combination. Hypothermia in trauma begins at 36°C as opposed to isolated hypothermia from environmental exposure, which begins at 35°C. Mortality rates are as high as 40% in trauma patients with temperatures of 34°C and approach 100% when the patient’s temperature is less than 32°C [51]. Hypothermia of the abdominal trauma patient is usually
multifactorial. Patients may arrive hypothermic from exposure and shock. Further exposure to cold environments in the emergency department (ED) or the operating room (OR) worsens this problem; other factors include the infusion of cold fluids and blood products, and an open peritoneal cavity in the operating room. Inadequate oxygen delivery leads to a failure of heat production. Vasodilation from either intoxicants or anesthetic agents and loss of shivering ability from muscle relaxants also aggravate the situation. It is critical to prevent the development of hypothermia because it is difficult to correct once present.

However, despite efforts in the ED and the OR, many damage control patients will be delivered to the ICU already hypothermic. In this circumstance, aggressive efforts must be employed, including raising the room temperature, ensuring the patient is covered with blankets, warming blankets, and warming all intravenous fluids and blood products administered. Lavage of the stomach via the nasogastric tube or lavage of the pleural cavity via the chest tube with warm saline solution may be considered. In severe cases of hypothermia, it may be appropriate to utilize continuous arteriovenous rewarming as described by Gentilello et al. [57]. The inability to correct hypothermia if these measures have been employed usually indicates a failure of adequate resuscitation.

Coagulopathy

The cause of coagulopathy of trauma, as with many other conditions, is multifactorial. The attributed etiologies include consumption of coagulation factors from hemorrhage as well as dilution from infusion of crystalloids. Hypothermia and acidosis play an important part in the coagulation cascade because enzymatic processes function poorly outside of the homeostatic normal, as was discussed in previous sections. Hypothermia and acidosis should be corrected to reduce the coagulopathy.

However, blunt trauma, and, in particular, crush injury, is associated with coagulopathy from tissue injury. These patients may arrive at the hospital already coagulopathic. In fact, up to 25% of patients arrive coagulopathic; this coagulopathy is associated with higher injury severity scores and predicts worse outcomes [58].

On arrival in the ICU from the initial phase of damage control surgery, blood should immediately be sent to the laboratory for prothrombin time, activated partial thromboplastin time, platelet count, and fibrinogen level. Thromboelastography has become more widely used and is
advocated by some centers as a better and more rapid assessment of coagulopathy and a way to determine which components of the coagulation cascade to replace.
SUMMARY

This chapter focuses on the unique aspects of critically ill abdominal trauma patients. With the increased use of nonoperative management and damage control resuscitation, the role of the intensivist has changed. The ICU must monitor closely for hemorrhage, signaling the failure of nonoperative management of solid organ injuries. All injuries may not have been identified prior to admission to the ICU, and a high index of suspicion must be maintained for missed injuries that are not readily apparent at presentation and are not easily found on the initial CT scan. For damage control resuscitation, the correction of hypovolemia, hypothermia, acidosis, and coagulopathy occurs as the patient transitions between the ED, the OR, and the ICU.

Epidemiology

With an annual attributable mortality of more than 100,000 people in the United States, blunt and penetrating trauma is a leading cause of death for Americans younger than 45 years of age and results in staggering losses of health among surviving trauma patients [1]. Trauma evacuation systems have improved dramatically over the past few decades, and patients are much more likely to survive injuries that would have previously resulted in early mortality. Many polytraumatized patients sustain significant orthopedic injuries. These need to be recognized and addressed appropriately to minimize consequent morbidity and mortality. A dedicated orthopedic trauma service, specifically constructed to manage patients with complex fractures and dislocations in the setting of other systemic injuries, may be associated with improved outcomes for trauma patients [2]. The orthopedic traumatologist is not only trained in the surgical management of the individual orthopedic injuries, but is also comfortable functioning as a member of a multidisciplinary team that may include emergency physicians, anesthesiologists, general surgeons, neurosurgeons, urologists, and plastic surgeons.

Musculoskeletal injuries of trauma patients come in many varieties. Long-bone fractures can have direct impact upon a patient’s early mortality and late morbidity. Pelvic fractures are associated with early mortality, and their recognition and acute management is vital as part of the life-saving efforts of the trauma team. Open fractures are associated with the development of sepsis if not properly managed. Articular (joint) fractures represent complex injuries requiring prolonged reconstruction; although they routinely occur among polytraumatized patients, their management is beyond the scope of this discussion. Compartment
syndrome, a sequela of severe extremity trauma, is a soft tissue condition that can result in early morbidity, associated with the impact of myonecrosis on renal function, as well as late disability, associated with fibrosis of one or more muscles important for activities of daily living. Venous thromboembolism (VTE) is a danger for all trauma patients, and the risk of VTE has been shown to be increased significantly among patients with pelvic and hip fractures. Finally, lesser fractures can have dramatic implications on future function for trauma patients; it has been shown that failure to identify and/or address complex injuries of the foot, for example, is associated with poor long-term outcomes among patients who survive major trauma [3].

In this chapter, we will introduce challenges and share knowledge associated with multiple problems that affect trauma patients: Open fractures, pelvic fractures, long-bone fractures, knee dislocations, compartment syndrome, deep venous thrombosis (DVT), and neurological injury. It is our goal to discuss orthopedic treatment considerations for all of these trauma sequelae such that they can be integrated into the management of the patient who is the victim of polytrauma.
OPEN FRACTURES

Open fractures, or fractures with associated skin wounds allowing communication of the external environment with the fractured bone surfaces, are present in a high percentage of polytraumatized patients. These wounds are at high risk for infection without adequate and early treatment of the open wound. The basic treatment protocol for open fractures includes antibiotic administration, wound debridement, wound irrigation, fracture stabilization, and wound closure.

Initially published in 1976 [4], the Gustilo–Anderson classification scheme is an imperfect but widely utilized classification for open fractures. Type I open fractures are fractures with a clean wound measuring less than 1 cm in length. Type II open fractures are fractures with a laceration measuring more than 1 cm in length and without extensive soft tissue damage. Type III open fractures are fractures with extensive soft tissue damage or an open segmental fracture (a two-level fracture of the same long bone). Type III fractures, therefore, represented a highly heterogeneous group of severe open fractures; a modification of the classification scheme for type III open fractures was therefore developed and published in 1981 [5]. Type IIIA open fractures have extensive soft tissue damage but adequate soft tissue coverage, or are the result of high-energy trauma irrespective of laceration size. Type IIIB open fractures entail extensive soft tissue loss, periosteal stripping, bone exposure, and massive contamination. No mention of requirement for muscle flap fracture coverage is made by the authors (despite the fact that many of these wounds indeed do require flap coverage); this is a modification of the classification that has been propagated over the years [6], although it was suggested by Gustilo himself in a subsequent letter to the editors of the Journal of Bone and Joint Surgery [7]. Type IIIC open fractures are those associated with a vascular injury that requires repair. An important point must be made about this classification scheme: It is best utilized during operative debridement of the open fracture. The presence of a small open wound in the skin may belie the extensive soft tissue injury underneath, leading to a misclassification of the open fracture. The reliability of this classification scheme has hence been questioned [8–10]. Regardless, this system continues to be used at many institutions.

As infection is a feared complication of open fractures, antibiotic
administration is crucial for decreasing rates of infection after open fractures [11]. Short courses of first-generation cephalosporins (typically, cefazolin), initiated as soon as possible after injury, are beneficial for limiting infections after open fracture [12]. Aminoglycosides and penicillins are often utilized in the treatment of type III open fractures and highly contaminated open fractures [13], respectively. Older studies have demonstrated that administration of broad-spectrum antibiotics lead to decreased infection rates [14]. However, the scientific evidence for this practice is limited [12]. Administration of aminoglycosides for the treatment of open fractures must be accomplished judiciously to minimize risk of oto- and nephrotoxicity. Quinolone antibiotics, effective against gram-negative bacteria, have been shown to be effective for reducing infection rates for type I and type II open fractures [15], but they may have an adverse effect on fracture healing, an effect suggested by animal studies [16,17]. Duration of antibiotic administration is a matter of debate. Older recommendations included 72 hours of antibiotic treatment for type I and type II open fractures and 120 hours for type III open fractures [18]; however, newer studies have demonstrated potentially equivalent outcomes in patients who have 24 hours of antibiotic therapy [19].

Surgical debridement of open fracture wounds in a complete and expeditious manner is an important additional factor for successful management. Sharp debridement should be meticulous, and all foreign material removed. Bone ends should be delivered into the wound, and complete exploration of the injury zone is necessary. Long longitudinal extensions of the traumatic wound are often necessary for adequate exploration. All tissue which is completely devitalized, including bone fragments devoid of soft tissue attachments, should be removed [20,21]. Judgments related to the removal of large articular (i.e., joint surface) fragments may be required to balance the risk of severe disability from the loss of said fragments versus the risk of infection with their retention. Devitalized extra-articular fragments can be cleaned and used as a reduction aid intraoperatively when fixation is proceeding immediately, or they may be stored and utilized later when fixation is delayed [22]. In general, therefore, it is better not to discard bone fragments from open fractures until the patient has arrived in the operating room for definitive management.

An ongoing source of debate for the management of open fractures relates to the timing of debridement. The previous benchmark that had been followed internationally is for open fractures to undergo urgent irrigation and debridement procedures within 6 hours. However, this has recently been questioned, as it appears to have little scientific evidence supporting it. In a seminal article on treatment of open fractures, Patzakis and Wilkins [14] demonstrated no relationship between the time
from injury to surgical debridement of open fractures and subsequent development of infection. Another more recent prospective observational study of open fracture patients across eight trauma centers in the United States also failed to show a correlation between time to surgical debridement and the risk of infection of open fracture wounds [23]. Although urgency of treatment for open fractures associated with massive contamination, vascular injury, and/or limb crush is self-evident, routine emergent management does not appear to be required for open fractures, and after-hours surgery done in a hurried fashion by underexperienced practitioners and teams may result in increased rates of minor complications [24]. However, it is generally accepted among the international community that treatment of an open fracture is not an elective procedure [25].

Wound irrigation follows sharp debridement. Irrigation solutions generally are based upon normal saline (0.9% NaCl). Additives historically have included bacitracin, cefazolin, neomycin, soaps, bleach, Betadine, and other antiseptics (such as benzalkonium chloride). Some of these, such as antiseptics, have been shown to be detrimental to wound viability [26]. Antibiotics appear to offer no benefit over normal saline alone [27]. High- versus low-pressure lavage for open fracture wounds has also been a source of debate. However, much of the debate on additives to irrigant solutions and the role of high-pressure saline have been put to rest, as a recent randomized control trial that failed to demonstrate any benefit to soap additives, and showed similar outcomes with high- or low-pressure washing. No consensus exists on the volume of irrigant. Protocols vary between institutions and even within institutions, based on surgeon preference. Up to 9 L of irrigant are utilized in some centers, but there is no scientific evidence upon which a recommendation can be based. Ultimately, it is the opinion of most surgeons that wound debridement is the most critical aspect of treating open fracture wounds, and that the irrigation component of this treatment is of relatively less importance.

Methods of fixation for open fractures are variable. Historically, acute open reduction and internal fixation of open fractures was contraindicated, without good scientific evidence. However, the Harborview group in Seattle demonstrated that acute open reduction and internal fixation of open ankle fractures is a safe and effective method of treatment [28]. External fixation is relatively rapid and fixation points can be kept out of the zone of injury. Mobilization of fracture ends can be accomplished at the time of future debridement, if necessary, and staged open reduction and internal fixation with external fixator removal is safe and effective [29–31]. Plate or nail fixation at the time of irrigation and debridement is also safe and effective [28,32], but limits the surgeon’s ability to redischace bone ends for wound exploration if repeat
debridement is indicated.

Early wound closure or coverage is preferred, as this appears to limit rates of infection of open fracture wounds [33]. Acute primary closure of open fracture wounds after debridement and fixation, if possible, has been shown to be a safe method of treatment [34]. Early coverage of open fracture wounds that are unable to be closed primarily has also been shown to be safe and effective [35]. Adjuncts to wound closure, especially in the setting of skin tension, include “pie-crusting” of skin about the wound(s) [36] or performing open wound management with a vessel loop closure technique to reapproximate wound edges [37] and/or use of negative-pressure wound dressings [38,39]. Also, if doubts about the safety of closure at the time of initial debridement and fixation persist, then open wound management and repeat debridement are appropriate until closure or coverage is considered safe. Negative-pressure wound dressings can be utilized successfully for open fracture wounds as a bridge to delayed closure with successful reduction of infection rates in some series [40], or as a bridge to delayed free tissue transfer with reduction of infection rates as compared to traditional dressings [41], perhaps allowing for a possible reduction of the need for free tissue transfer [42]. However, this may be a limited process, and earlier wound closure or flap coverage may reduce infection rates over late wound closure or coverage, despite utilization of the negative-pressure dressing [43].

Occasionally, the polytraumatized patient who sustains high-energy open fractures may not be a candidate for fixation, instead requiring amputation. Properly indicated, a well-executed amputation can be a life-saving procedure that can shorten rehabilitation times associated with prolonged reconstruction of a mangled extremity. The debate often centers on whether a limb might be amenable to salvage versus amputation at the time of the patient’s arrival to the hospital. Errors in judgment regarding this can have devastating effects to the patient’s outcome, both physiologically and psychologically. Multiple assessment tools have been developed to assist surgeons with making decisions regarding limb salvage versus amputation, including the Mangled Extremity Severity Score (MESS) [44,45] (Table 45.1). However, many of these tools are mediocre at best with regard to their predictive value. One example is the Lower Extremity Assessment Project (LEAP) [46,47]. A historically held indication for acute amputation in the setting of a mangled extremity, the lack of plantar foot sensation, has been refuted by the LEAP study team; many patients presenting with absent plantar foot
sensation recovered it completely over time, indicating that the most tibial nerve injuries are neurapraxias (as opposed to complete disruptions) [48]. Ultimately, each injured patient must be carefully scrutinized, and no particular physical examination finding or trauma scale has been shown to be absolutely predictive of the success or failure of attempts at limb salvage. Therefore, thoughtful interpretation of trauma scores combined with assessment of the patient’s functional goals is imperative prior to making the choice between salvage and amputation.

BP, blood pressure; CR, capillary refill; GSW, gunshot wound; IV, intravenous; MESS, mangled extremity severity score; OR, operating room.
PELVIC FRACTURES

Evaluation

The pelvis contains the acetabulae, which represent the articulations with the lower extremities, and the lumbosacral junction, representing the articulation with the spine. Comprised of three bones (two hipbones and the sacrum) with three articulations (two sacroiliac joints and the pubic symphysis), the pelvic ring is designed to distribute the weight of the upper body onto the legs for bipedal ambulation. The sacroiliac joints and pubic symphysis are thought to have minimal motion, and are connected by stout ligaments. Incompetence of these joints can lead to laxity and chronic pain. This may occur after trauma, complicated vaginal birth in females, or idiopathically [49,50]. Further ligamentous connection between the posterior and anterior pelvis is provided by the sacrospinous and sacrotuberous ligaments. The transverse processes of the fifth lumbar vertebra are attached to the posterior iliac crests by the iliolumbar ligaments.

Disruption of the pelvic ring of young patients requires a high-energy mechanism, such as a motor vehicle crash or fall from a significant height. As the pelvis is functionally a single rigid ring, the discovery of a single break is a harbinger for others. For example, pubic ramus fractures, in the anterior aspect of the pelvic ring, may be obvious on plain radiographs, but associated sacral fractures may not be readily apparent on plain radiographs due to the overlying bowel gas, radio-opaque contrast agents in the bowel or bladder, or bony anatomy. A high index of suspicion must be maintained, and further injury may be visible on computed tomography (CT) scanning. It should also be emphasized that transverse acetabular fractures often represent a component of a pelvic ring disruption, and suspicion that such disruption has occurred should be maintained with these fracture patterns.

Multiple classification schemes exist that describe various aspects of pelvic ring injuries. The Young and Burgess [51] classification (Table 45.2) is the most commonly utilized descriptive scheme for pelvic ring injuries, in which they are classified as anteroposterior compression (APC) injuries, lateral compression (LC) injuries, vertical shear (VS) injuries, and “complex patterns”. This classification can be helpful for identification of other problems that can be associated with the pelvic
ring injury, such as increased incidence of head trauma with LC injuries and of abdominal and chest trauma with APC injuries [52], and it can be somewhat predictive of transfusion requirements in trauma patients [53]. Other commonly utilized classification schemes include the Tile classification [54] and the American Orthopedic (AO)/Orthopedic Trauma Association classification [55]. No pelvic fracture classification scheme, however, possesses all seven of the following requisites for universally applicable schemes: Ease of use, prognostic value (outcomes), descriptive value (describe the injury), therapeutic value (direct treatment), research value (allows direct comparison between groups), intraobserver reliability, and interobserver reliability.

Orthopedic examination of the pelvic fracture patient is similar to the orthopedic examination of all polytraumatized patients, covering the entire musculoskeletal system in a methodical manner. Focused examination of the pelvis includes observation of limb deformity; abnormal limb rotation or shortening in the setting of pelvis injury may be secondary either to pelvic deformity or to hip dislocation (with or without associated acetabular fracture), or to extrapelvic lower extremity fracture. Skin about the pelvis, including about the perineum, must be carefully examined for lacerations that can be associated with open pelvic fractures. Open wounds may be present within folds of skin, and a thorough examination is necessary. Lacerations may lurk within the fold of skin inferior to the scrotum in males, and examination of this area
cannot be neglected. Extensive ecchymosis should be noted; these may be indicative of degloving injuries. Blood emanating from the anus or vagina can be an indicator of open pelvic fracture. Digital rectal examination is therefore required to detect occult open fractures into the rectum, and vaginal examination should be performed in a safe manner to detect open fractures violating the vaginal vault. Speculum examination is not generally performed in the trauma bay. Urethral disruptions can also occur with pelvic fracture, and blood at the urethral meatus can be indicative of such an injury. Manual palpation of the pelvis and gentle compression of the iliac crests may detect abnormal motion or crepitus associated with an unstable disruption of the pelvic ring, although this manipulation lacks sensitivity and specificity [56]. Pelvic manipulations must be undertaken judiciously; unstable pelvic ring disruptions can cause life-threatening hemorrhage, which can be exacerbated by repeated examinations. Repeated examinations also can induce severe patient discomfort. A neurovascular examination of both legs, as well as examination of anal sphincter tone and of the bulbocavernosus reflex, is routine.

Standard radiography of the pelvis begins with the anteroposterior view. The inlet radiograph, with the beam tilted approximately 40° caudal, can detect anteroposterior translation of the hemipelvis and rotational hemipelvic deformities. The outlet radiographs, with the beam tilted approximately 40° cephalad, can detect “vertical” translation (more often, a flexion deformity) of the hemipelvis and is useful for visualizing sacral fractures. Judet radiographs, with the patient or X-ray beam tilted approximately 45° to either side, are reserved for patients with acetabular fractures detected on anteroposterior radiographs. CT has become routine for polytraumatized patients, and provides extensive information regarding the bony anatomy of a pelvic fracture and/or dislocation. In the setting of pelvic and acetabular fractures, CT scanning is also invaluable for planning of the surgical reconstruction. The CT scan is of limited utility, however, for acetabular fractures if the hip remains dislocated during the scan. Therefore, it is desirable to reduce fracture–dislocations of the hip (acetabulum) prior to CT scanning of the pelvis for adequate delineation of fracture anatomy and for preoperative planning.

**Acute Management**

Pelvic fracture patients often have multiple associated injuries, all of which may contribute to the overall physiological condition of the patient. Early mortality of patients with pelvic fractures may be related to patient age and occurs as a result of catastrophic hemorrhage, head injury, or multiple organ system failure [57,58]. As the pelvic fracture may contribute directly to morbidity and mortality, early stabilization is
preferred. This stabilization may be performed at the scene of the injury by emergency medical personnel, by the application of a circumferential sheet, pelvic binder, or other compressive garment. Sheets are readily available, inexpensive, and easy to apply [59]. The personnel applying the sheet should do their best to avoid wrinkling of the sheet, which may cause skin compromise [60]. Overcompression of the pelvic ring must be avoided, as the exact nature of the pelvic injury is unknown; overcompression of certain types of unstable fracture patterns may lead to laceration of the bladder, rectum, vagina, or other intrapelvic structures. Although circumferential pelvic wraps may assist with patient transport and comfort and can successfully reduce some types of pelvic ring disruptions [61], some studies fail to demonstrate decreases of mortality, transfusion requirements, or the need for pelvic angiography by their use [62].

Upon arrival at the trauma center, all circumferential clothing (including pelvic wraps/binders) is removed to allow for examination of the lower abdomen and pelvis. Binders can be reapplied after examination, and an effort should be made to keep patients warm to avoid coagulopathy. Although pelvic fractures may be associated with catastrophic hemorrhage, ongoing hemodynamic instability can arise from a number of causes unrelated to the specific pelvic injury. Grossly unstable pelvic injuries can be treated provisionally with the application of skeletal traction, on the same side(s) of the pelvic injury(ies), through either the distal femur or the proximal tibia as the side of pelvic instability. Skeletal traction is also used routinely for the provisional stabilization of acetabular fractures prior to definitive treatment in the operating room; traction can minimize contact of the femoral head with rough acetabular fracture edges.

Patients with pelvic ring disruptions may demonstrate hemodynamic instability that is refractory to volume resuscitation. An ongoing search for sources of blood loss is vital. One publication demonstrated that, at a single trauma center, 21% of patients with pelvic fractures and hemodynamic instability (systolic blood pressure < 90 mm Hg) refractory to a 2 L bolus of saline ultimately expired, and 75% of those patients expired as a result of exsanguination [63]. Unstable pelvic fractures are more highly associated with pelvic hemorrhage than are stable pelvic fractures. Therefore, investigation of other potential sources of hemorrhage is vital, especially for the hemodynamically unstable trauma patient with a stable pelvic fracture pattern [64]. Patients with unstable APC injuries have been demonstrated to require massive transfusions,
followed by those patients with VS or complex mechanism pelvic ring disruptions, and lastly by those with LC injuries [53,65]. However, fracture pattern may not always be indicative of transfusion requirements or the need for angiographic arterial embolization [66].

Pelvic fracture-associated bleeding comes from three sources: Fracture surfaces, lacerated or ruptured veins, or lacerated or ruptured arteries. Fracture surfaces may not be a source of ongoing massive blood loss, and therefore may contribute negligibly to hemodynamic instability [67]. Distinguishing between major sources of pelvic hemorrhage—arterial or venous—represents a challenging but important task, and prior studies have examined multiple factors that may be associated with successful angiographic embolization, used for arterial hemorrhage, including patient age, trauma scores, shock on arrival to the trauma center, and fracture pattern [68]. Venous hemorrhage after pelvic fracture can be adequately treated with pelvic stabilization, either by circumferential pelvic wrap or by external fixation, while arterial hemorrhage can be addressed with angiographic embolization [69]. Transient response to initial resuscitation, lack of response to provisional pelvic stabilization, and presence of a contrast blush on pelvic CT scanning are all thought to be indicative of arterial hemorrhage that may be amenable to angiographic embolization [70,71].

Pelvic packing has been used for control of severe hemorrhage in hemodynamically unstable patients. It has been proposed that packing may be a more reliable method of treating severe pelvic fracture-associated hemorrhage than angiographic embolization with regard to controlling continued hemorrhage and limiting patient death due to exsanguination [72]. Angiography may also be delayed, and emergency stabilization of the fracture along with or without pelvic packing may be more reliable at controlling severe fracture-associated hemorrhage [73]. Another series documented a 30-day survival rate for pelvic fracture patients treated with extraperitoneal pelvic packing of 72%, and subsequent angiography was successful in detecting arterial hemorrhage in 80% of the patients after packing. Immediate increases in systolic blood pressure after packing were also noted [74]. Importantly, both angiography and pelvic packing must be used in a judicious fashion; this will help minimize complications related to both (such as gluteal necrosis).

Genitourinary injuries occur in a small subset of patients with pelvic fracture. This frequency has been shown to approximate 4.6% in a study of the U.S.A. National Trauma Data Bank [75]. Another recent study estimated a genitourinary injury rate of 6.8% in pelvic fractures; importantly, 23% of these injuries were missed at the time of initial evaluation [76]. Urological injuries most commonly take the form of urethral disruption, extraperitoneal bladder rupture, or intraperitoneal
bladder rupture. Diagnosis is often by retrograde cystourethrogram, with careful attention to postdrainage images to detect bladder ruptures not detectable when the bladder is filled with contrast [77]. Urethral disruption appears to occur distal to the urogenital diaphragm, contrary to classical teaching [78]. Primary realignment, when possible, is accomplished endoscopically followed by threading of the urinary catheter by the Seldinger technique [79]. This repair may be accomplished at the time of pelvic fracture repair, using a team approach [80]. Routine use of suprapubic catheters for the management of urethral disruptions is discouraged, as it may increase the rate of infection, especially in the setting of open reduction and internal fixation of anterior pelvic ring injuries [81]. Bladder injuries are more commonly extraperitoneal. Nearly all present with gross hematuria. Intraperitoneal bladder ruptures are generally treated with surgical exploration, to delineate the extent of injury fully, and with Foley (preferred if open reduction and internal fixation of the pelvic ring fractures will be accomplished) or suprapubic catheters. Extraperitoneal ruptures may be managed with Foley catheters; the bulk of these require no formal repair [82]. However, if open reduction and internal fixation of the pelvic fracture is planned, then primary repair of the extraperitoneal rupture is also accomplished at the same time, with low rates of infection [80].

Open pelvic fractures represent a subset of severe injuries with a historically high mortality rates. A recent systematic review calculated the total mortality rate in open pelvic fracture patients across multiple published series prior to 1991 as 30%, and since 1991 as 18%, with the decrease likely owing to aggressive management of the pelvic fracture, selective diversion of the fecal stream, and advances in critical care medicine [83]. These open fractures may be occult, localized within the rectum or vagina. Visual as well as digital exploration is mandatory in these patients. Examination of bowel contents for gross or occult blood is also necessary. While selective fecal diversion does appear beneficial for open pelvic fracture patients with perineal wounds or for patients with extensive or posterior wounds, routine use of fecal diversion does not appear to reduce infection rates among patients with open pelvic fractures [84,85].
LONG-BONE FRACTURES

Femoral Shaft Fractures

Femoral shaft fractures often occur in conjunction with other injuries after high-velocity blunt or penetrating trauma. Fracture of the femur is associated with significant morbidity of the polytraumatized patient; significant hemorrhage can occur, even in the absence of open wounds. Bilateral femoral shaft fractures are associated with higher mortality rates than are seen in patients with unilateral femoral shaft fractures [86]. Open femoral shaft fractures are unusual and require significant energy to create the situation where the fracture fragments travel through the robust soft tissue envelope of the thigh.

Initial management of femoral shaft fractures often entails placement of traction devices in the field. These devices are meant to be portable, and they rest against the ischial tuberosity, against which they provide traction through the ankle or the foot. Splinting of femoral shaft fractures is marginally effective at best, as it requires a splint to include the trunk for effective immobilization. Portable traction devices should be removed as quickly as possible to prevent sciatic nerve pressure injury or skin ulceration. Skin or, more commonly, skeletal traction is routinely applied in the emergency department, as a temporizing measure prior to transport to the operating room and to allow for continued evaluation of the patient for other injuries. This traction provides patient comfort, provides immobilization for the fracture, and limits fracture shortening. It can also function as a temporary treatment modality in the setting of operating room unavailability. Evaluation of the patient prior to transport to the operating room should include an investigation of the ipsilateral femoral neck with thorough radiographic imaging. A high percentage of femoral neck fractures are missed in the setting of ipsilateral femoral shaft fractures, and CT scans do not appear to be 100% sensitive for their diagnosis [88].

Operative management is the mainstay of therapy for fractures of the femoral shaft. In the United States, definitive treatment of the femoral shaft fracture patient in skeletal traction is of historical interest only. A distinct advantage of femur fracture stabilization includes the ability to mobilize the patient, thereby avoiding complications associated with prolonged bed rest in critically injured patients, such as pneumonia,
pressure ulcers, and deep vein thrombosis. The gold standard for treatment of closed fractures of the femoral shaft is reamed, statically locked, antegrade (from the hip region) medullary nailing. This method of treatment has been demonstrated to be highly effective in numerous studies [88–90], and it can allow for early unprotected weight-bearing [91]. Reaming prior to nailing appears to improve healing rates of femoral shaft fractures [92,93], although this may come at the expense of increased pulmonary injury in the setting of chest-injured patients [94].

Other methods of fixation for femoral shaft fractures include open reduction and internal fixation with a plate-and-screw construct and external fixation. Plate fixation is often reserved for extremely proximal or extremely distal femoral shaft fractures and for fractures in which intramedullary fixation is contraindicated (e.g., the presence of device, such as a total hip arthroplasty stem, within the femoral canal). Plate fixation has been employed successfully for polytraumatized patients with femoral shaft fractures [95].

Early femoral shaft stabilization is associated with improved outcomes among polytraumatized patients [96]. The method of stabilization is unimportant for these early outcomes; medullary nailing, plate-and-screw fixation, or external fixation provides benefit. Controversy remains regarding the optimal method of early femur fracture stabilization for the polytraumatized patient, including chest- and head-injured patients. The Hannover group has published extensively regarding the second-hit phenomenon of femoral nailing in polytraumatized patients, and has made recommendations that pulmonary- and head-injured patients perhaps undergo acute “damage-control orthopedic surgery” with external fixation of a femoral shaft fracture, followed by staged conversion from external fixation to medullary nailing when the patient’s condition has improved and resuscitation has been completed [97–99]. However, some recent studies have demonstrated that reduced rates of acute respiratory distress syndrome (ARDS) can be achieved with acute nailing of femoral shaft fractures, instead of with damage-control orthopedics, for polytraumatized patients [100–102]. The utilization of reaming has been shown not to create increased rates of ARDS among polytraumatized patients undergoing medullary nailing of femur fractures, as compared to patients undergoing nailing without reaming [100]. Adequate resuscitation has been shown to be important prior to nailing [100].

**Tibial Shaft Fractures**

Fractures of the tibial shaft are common among polytraumatized individuals. Tibial fractures have a higher likelihood of being open [103,104], perhaps secondary to the thin soft tissue envelope surrounding
the human tibia. This soft tissue envelope may also play a role for the increased likelihood of infection and nonunion for tibial fractures; infected nonunion is more common after tibial fracture than after any other fracture of a long bone [105]. Compartment syndrome is also common after high-energy fractures of the tibia, even when the fractures are open [10].

Principles of treatment for tibial shaft fractures are similar to those of femoral shaft fractures: Provide comfort, restore length, alignment, and rotation, and allow for early mobilization. Tibial fractures are commonly treated with medullary nailing techniques, unless there is intra-articular involvement. Nailing of tibial fractures can provide sufficient stability to allow for full weight-bearing after surgery [106]. Plating of tibial fractures is often done for those fractures that involve the articular surfaces of the tibia. External fixation is most often utilized in a temporary fashion, especially with large open wounds requiring repeat debridement, of complex fractures involving the tibial plateau or tibial plafond, or for patients with significant physiological instability. Conversion of external fixation to nailing is safe, when the patient’s condition permits [30,31].

Tibial fractures in patients sustaining multisystem trauma can be stabilized in a delayed fashion, after the physiological condition of the patient has improved. Unlike femoral shaft fractures, tibial fractures can be effectively treated temporarily with long-leg splints. However, splinted tibial fractures must be carefully monitored for skin breakdown from the splinting material, compartment syndrome, and impending skin compromise from unstable fracture ends.

Humeral Shaft Fractures

Fractures of the humeral shaft are a source of morbidity among polytraumatized patients. They have implications for early rehabilitation as well as for future function. Humeral shaft fractures can be complicated by brachial artery and nerve injuries; the radial nerve is particularly susceptible to concomitant injury with humeral shaft fracture. Management of humeral shaft fractures and their sequelae are based upon the overall condition of the patient and on nature of the injury.

Isolated humeral shaft fractures are particularly amenable to closed management. Splinting, casting, and fracture bracing have all been noted to be highly successful in achieving union of humerus fractures [107,108], and long-term outcomes (at a minimum of 1 year) are thought to be as good as those after surgical repair [109]. Considerations for the management of humerus fractures of polytraumatized patients, however, likely are different.

Polytraumatized patients often require the use of both arms for effective mobilization and rehabilitation. They are subjected to prolonged
bed rest, and may be incapable of the frequent fracture brace adjustment that is advocated by Sarmiento and colleagues [107]. As fracture braces are not generally utilized during the acute phase after fracture (delay of 1 to 3 weeks prior to application is common), early splints can be cumbersome and unwieldy for patients and caregivers and are not generally removable for the purposes of skin monitoring and vascular access. Obtunded patients also cannot complain about pressure points beneath a nonremovable splint, and they do not routinely change position in an effort to alleviate pressure points. Skin necrosis can be a danger in this setting. For all of these reasons, management of humeral shaft fractures for polytraumatized patients is typically operative.

Humerus fractures can be treated either with open reduction and internal fixation, utilizing a plate-and-screw construct, or with medullary nailing. Advocates of plate-and-screw fixation cite the ability of humeral shaft fracture patients to utilize their arms for assistance with ambulation (i.e., weight-bearing on crutches or a walker) after fixation [110]. Advocates of medullary nailing for humeral shaft fractures have demonstrated good outcomes [111], although no literature exists that provides evidence regarding immediate weight-bearing after nailing of humerus fractures. Some literature exists that appears to favor plating versus nailing for humeral shaft fractures, as shoulder impingement and reoperation risk appear to be lower with plating [112–114], although there is no definitive answer regarding optimal surgical treatment of humeral shaft fractures. In the setting of radial nerve palsy, present between 8% and 11% of the time [115,116], nerve exploration can also occur at the time of surgery. However, radial nerve palsy is not an indication for operative exploration of the nerve [117]; the bulk of radial nerve palsies appear to be neurapraxias, and one study reported that 89% recover normal distal neurological function after closed humeral shaft fracture management [118].

Forearm Fractures

Forearm fractures, while not often a contributing factor to mortality of the polytraumatized patient, are a source of long-term morbidity if not properly addressed. The forearm functions as a mobile unit that is dependent upon the anatomy of the radius and the ulna. The radius and ulna are “parallel” but curved bones, and this anatomy is vital for the maintenance of proper forearm pronation and supination. The maximal radial bow has been shown, in anatomical studies, to be approximately 16 mm and located near the junction between the middle and distal one-
thirds of the forearm length [119]. Encroachment of either bone or of foreign material into this region may have adverse consequences on forearm rotation, and may create limitations of pronation, supination, or both.

Fracture of one bone of the adult forearm often leads to injury associated with the other bone, whether it is fracture or dislocation of the other bone. Dislocation, when it occurs, is either at the elbow (radius) or wrist (ulna). The anatomical connections between the radius and ulna include the proximal and distal radioulnar joints and the interosseous ligaments; deformation of one bone, due to fracture, that is not “compensated” by fracture of the other bone will cause the other bone to be drawn in the direction of the deformation, causing dislocation. Typical patterns include displaced proximal ulnar shaft fractures associated with dislocations of the radial head from the capitellum (the “Monteggia” fracture–dislocation) and displaced distal radial shaft fractures associated with dislocations of the ulnar head from the distal radioulnar joint (the “Galeazzi” fracture–dislocation).

Careful scrutiny of the elbow, forearm, and wrist is vital for the detection of these injuries, which may be overlooked in the setting of multiple traumas. Failure to recognize these injuries acutely can result in increased difficulty with surgical reconstruction (if accomplished late) or significant disability (if reconstruction is never accomplished). Forearm fractures tend to shorten, due to the powerful investing musculature of the forearm, and surgical repair is often more straightforward when it can be undertaken within a few days of injury. The repaired forearm is often protected and weight-bearing is restricted for a number of weeks. However, “platform” walkers or crutches may be utilized for assistance with ambulation for many cases; the weight of assisted ambulation is borne through the elbow (as opposed to the wrist and forearm) with these devices.
COMPARTMENT SYNDROMES

Muscle groups are divided into compartments by layers of noncompliant fascia. Injury to a particular muscular compartment can induce edema and/or hemorrhage within the compartment, leading to increased intracompartmental pressures. Increased intracompartmental pressure can lead to venous congestion and resultant muscle ischemia within the involved compartment(s). This scenario is termed “compartment syndrome.” The number of muscle compartments is variable based on location in the body. The brachium has two muscular compartments (anterior and posterior), the forearm has three muscular compartments (dorsal, volar, and mobile wad), the thigh has three muscular compartments (anterior, posterior, and adductor), and the leg has four muscular compartments (anterior, lateral, superficial posterior, and deep posterior) (Table 45.3). The exact number of muscular compartments in the hand and the foot are a matter of debate. Hand compartments include the interosseous compartments as well as the thenar and hypothenar compartments, and foot compartments include the interosseous compartments as well as the abductor and adductor compartments.

</table>
The absolute intracompartmental pressure at which a compartment syndrome exists continues to be a matter of debate. Some authors have previously advocated threshold intracompartmental pressures, such as absolute values of 30 mm Hg or 40 mm Hg, as diagnostic of compartment syndrome. However, a differential between intracompartmental pressure and diastolic blood pressure is thought to be a more reliable indicator of evolving compartment syndrome. The pressure differential thought to be diagnostic of compartment syndrome is commonly accepted to be 30 mm Hg [120]. The improved reliability of ΔP measurements, as opposed to absolute measurements of intracompartmental pressures alone, was recently illustrated in a series of 101 tibial fracture patients. In this series, 41 patients had continuous leg intramuscular compartment pressures more than 30 mm Hg for over 6 hours in the setting of a satisfactory ΔP. No difference in outcome regarding return to function and muscle strength was noted, as compared to a control group of 60 patients without elevated intramuscular pressures [121].

Compartment syndrome is a problem that can arise among patients who have sustained high-energy injuries. Typical injuries associated with development of compartment syndrome include fractures, dislocations, crush injuries, and prolonged episodes of limb ischemia. The syndrome can also develop after reperfusion of a dysvascular limb that occurs after a revascularization procedure or after a manipulative reduction of a fracture that reduces kinking and occlusion of vessels. Penetrating injuries, such as gunshot and stab wounds, can lacerate arteries within a single compartment or multiple compartments, leading to hemorrhage under pressure into a confined environment and creating a compartment syndrome. The presence of a penetrating injury or open fracture (which results in fascial disruption) should not create a false sense that compartment syndrome will not develop; compartment syndromes have been documented to occur in the setting of penetrating injury or open fracture [122].

Compartment syndrome can also develop after stabilization of a fracture, such as after nailing a tibial fracture, once the compartment has been returned to its preinjury length and its available volume is thereby diminished. This “finger-trap” phenomenon was initially described in the literature by Matsen and Clawson [123]. Tibial traction or fracture...
reduction in the setting of tibial shaft fractures raises compartment pressures [124]. A fracture situation in which excessive shortening is corrected, or vigorous traction is required to maintain reduction, should perhaps prompt increased vigilance for the development of compartment syndrome. This risk must be balanced, however, during staged management of severe fractures, as the consequence of initial inadequate limb-length restoration may be increased difficulty of the definitive reconstructive procedure at the time of formal open reduction and internal fixation. Also, a recent report revealed that among tibial plateau fractures, application of an external fixator device that spans the knee and fracture may lead to transient elevations of intracompartmental pressure, but does not appear to cause a compartment syndrome [125].

Missed compartment syndromes can lead to significant morbidity. Frank muscle necrosis is a normal sequela of compartment syndrome, and associated joint contractures have been extensively described in the literature. Elevated levels of serum creatine phosphokinase (CPK) or the appearance of myoglobinuria (which can be misinterpreted as hematuria) are associated with muscle necrosis, and have been utilized in the past as diagnostic tools for evolving compartment syndromes [126,127]. Delayed treatment of compartment syndrome is fraught with complications [128]. Infection rates are dramatically increased when fasciotomy for compartment syndrome is delayed [129]. Fasciotomy revision, performed in a delayed fashion for inadequate index fasciotomy (and failure to relieve compartment syndrome), has been associated with increased rates of mortality and major amputation [130]. Often, it is not possible to determine the exact time of onset for a compartment syndrome. Therefore, the recommendation is that fasciotomy be undertaken as expeditiously as possible after diagnosis of compartment syndrome, and that a high index of suspicion for the development of compartment syndrome should be maintained in patients with high-energy trauma or trauma patients who are obtunded.

Compartment syndromes should be diagnosed during the evolution phase. A high clinical suspicion should be maintained for any patient who has sustained a high-energy injury. Pain out of proportion to the injury should alert the examiner to the possibility of impending compartment syndrome. Orthopedic injuries are very painful by their nature, and patients often have differing pain tolerances (sometimes affected by chronic narcotic use/abuse), so the examiner should be sensitive to changes in pain level as reported by the injured patient. Traditionally, the “five P’s” have been utilized in the awake, responsive patient for
examination of the leg and ruling out compartment syndrome: Pain with palpation of the compartment, pallor, paresthesia, pain with passive stretch, and pulselessness are commonly quoted as signs of compartment syndrome. Pulselessness, however, is an extreme late finding as it requires excessive pressures, in excess of systolic pressure, to occlude arteries and likely associated with complete myonecrosis within compartments involved. Excessive pain with passive stretch of muscles within each compartment should alert the examiner to evolving compartment syndrome. Awareness of the patient’s injuries and their direct contribution to pain with the motion of a joint (e.g., intra-articular fracture) should be considered. All compartments of a traumatized extremity should be examined. Muscle compartments tend to be very firm in the setting of evolving compartment syndrome.

Direct monitoring of intracompartmental pressure is possible utilizing the wick catheter technique, an arterial pressure line setup, or a variety of commercially available devices. These methods provide direct measurements of intracompartmental pressures in mm Hg. It should be emphasized, however, that compartment syndrome is primarily a clinical diagnosis. Physical examination findings consistent with evolving compartment syndrome should prompt surgical intervention, even in the setting of compartment pressure measurements that indicate normal ΔP, as the consequences of missed compartment syndrome include myonecrosis and irreversible neurological injury. Complete reliance upon direct intracompartmental measurements may result in undertreatment or overtreatment of compartment syndrome. Intracompartmental pressure measurements have been shown to be highest within 5 cm of the fracture, and measurements taken outside of this zone may be spuriously low and lead to undertreatment [131]. Also, there is a documented decrease in diastolic blood pressure after induction of general anesthesia; intracompartmental pressure measurements obtained in a patient under anesthetic must be interpreted cautiously as the ΔP value may be spuriously low and lead to overtreatment [132]. Diagnosis of compartment syndrome is variably difficult, even at large trauma centers [133], and high indices of suspicion need to be maintained in order to correctly identify and treat patients.

For obtunded patients, serial exams should be vigilantly completed. The examiner should note compartment firmness and proceed appropriately. Significant degrees of subcutaneous edema can mask tense compartments. Compartment pressure monitoring with commercially available devices or with an arterial pressure line setup may be utilized
for diagnosis in the obtunded patient, especially if the patient exhibits no response to painful stimuli and if physical examination of compartment tightness is impeded by extensive surrounding edema (e.g., with anasarca).

Techniques of fasciotomy have been described extensively. Adequate decompression of all compartments in the affected portion of the extremity is the goal. During fasciotomy, nonviable muscle is debrided. Following fasciotomy, closure of the fascia is not indicated and skin closure should be undertaken cautiously. It is imperative to verify that all compartments of the affected extremity have been released, regardless of the surgical approach utilized. Anatomy may be distorted due to fracture deformity, excessive hematoma, or soft tissue avulsion, and it occasionally can be difficult to discern fascial planes. Negative-pressure wound therapy devices may also be beneficial for promoting growth of granulation tissue within a fasciotomy bed, in anticipation of skin grafting, or in maintaining smaller wound dimensions, in anticipation of delayed primary closure [134,135].

Fasciotomy can be associated with both acute and long-term morbidity. Multiple neurovascular structures can be injured during fasciotomy. Risk can be minimized by careful and meticulous dissection technique, maintaining nerves and vessels within a cutaneous flap (if possible), and assuring that neither is directly exposed to the environment (dressing) at the conclusion of the case. At least one case of profound hemorrhage after erosion of an artery beneath a negative-pressure wound therapy device has been reported [136]. Analysis of long-term outcomes related to fasciotomy is difficult in the trauma setting due to the concomitant injuries that have invariably occurred and which can have an effect upon function. Nevertheless, a retrospective analysis of 40 patients undergoing leg fasciotomy for a variety of reasons has been published [137]. Complications of leg fasciotomy were common, and included neurological injury, hemorrhage, and infection. Only 45% of legs healed with a good functional result, and 27.5% had a severely disabled leg at the time of final healing. Another report indicated frequent patient complaints related to fasciotomy wounds, including decreased sensation, tethering of tendons, and recurrent ulceration [138]. Other known side effects of compartment release include pruritus, reflex sympathetic dystrophy, temperature sensitivity, venous stasis, and chronic edema. Despite these concerns, the morbidity and potential mortality of an untreated compartment syndrome is likely to be much higher. Also, a number of published reports, reviewed by Bong et al. [139], indicate that outcomes of fasciotomy for chronic exertional compartment syndrome (in the absence of trauma) are reliably good. These reports, however, require cautious interpretation for their application to trauma, as they did not include patients who required fasciotomy for trauma-related
compartment syndrome.
OTHER SEQUELAE OF ORTHOPEDIC TRAUMA

Deep Venous Thrombosis

Polytraumatized patients with lower extremity or pelvic fractures often are subjected to prolonged periods of immobilization or reduced mobility. They are at risk for development of DVT and subsequent pulmonary thromboembolism (PE). Management of the orthopedic trauma patient must take into account the increased propensity for these patients to develop VTE disease.

There has been much debate in the literature about appropriate methods of DVT prophylaxis for orthopedic trauma patients. The Eastern Association for the Surgery of Trauma (EAST) states that the greatest risk factors in trauma patients for development of VTE are spinal fractures and spinal cord injury. EAST also states that insufficient evidence exists regarding risk of VTE in trauma patients as it relates directly to long-bone fracture or pelvic fracture \[139\]. Trauma patients with pelvic and acetabular fractures are thought to have an increased risk of VTE \[140\]. However, there is limited high-quality evidence in the literature, regarding the best method of DVT prophylaxis \[141\].

Prophylaxis of trauma patients, especially those with pelvic and acetabular fractures, is important to reduce the risk of DVT. Trauma patients have been shown to have lower rates of DVT when both chemical and mechanical means of prophylaxis are utilized \[142\]. Mechanical DVT prophylaxis can consist of foot pumps or pneumatic compression devices. Chemical DVT prophylaxis often consists of low-molecular-weight heparin (LMWH) for hospital inpatients; for patients thought to be at higher risk of VTE and who are awaiting surgical intervention for fracture repair, chemical prophylaxis does not need to be halted in anticipation of surgery \[143\]. Despite adequate prophylaxis, however, patients are still at risk for development of DVT \[144\].

As there are not any high-quality studies that dictate practice guidelines, the Orthopedic Trauma Association put together the recommendations based on expert opinion \[145\]. These recommendations include the following:

1. Initiation of LMWH in patients with musculoskeletal injury, who do not have contraindications within 24 hours.
2. LMWH should be held for 12 hours prior and subsequent to surgery.
3. Patients should be started on both pharmacological and pneumatic compression devices if able.

4. If pharmacological prophylaxis is contraindicated, pneumatic compression devices should be used.

5. For patients at high risk for VTE, the panel recommended four weeks of prophylaxis.

6. Routine screening for DVT is not recommended for asymptomatic patients with musculoskeletal injuries.

7. Low-risk patients do not require routine inferior vena cava (IVC) filter placement.

8. Though patients with closed head injuries with stable neurological exams and stable head CT can be anticoagulated in 24 to 48 hours, a neurosurgical consultation is recommended. While these are current expert recommendations, the panel recommended that further high-quality studies are required [145].

---

Peripheral Nerve Injury

The bulk of peripheral nerve injuries that occur as a consequence of trauma are neurapraxias, which often will recover with time. Typical neurological injuries include radial nerve palsies in association with humeral shaft fractures, sciatic nerve palsies (peroneal branch, in particular) in association with pelvic and acetabular fractures, and brachial plexopathies in association with scapulothoracic dissociation.

Radial nerve palsies occur after approximately 12% of humeral shaft fractures [118]. An early description of radial nerve palsy in association with humeral shaft fracture was published by Holstein and Lewis, and describes the association with a spiral fracture of the humeral shaft located at the junction between the middle and distal one-thirds of the diaphysis [147]. The radial nerve supplies motor innervation to the extensors of the hand and wrist; patients with radial nerve motor palsies will lack the ability to extend the wrist or hyperextend the interphalangeal joint of the thumb, which is mediated by the extensor pollicis longus. The extensor digitorum communis (EDC), also supplied by the radial nerve, extends the metacarpophalangeal joints of the hand, but patients may recruit other muscles or perform other functions (such as wrist flexion) that will serve to extend the digits, even though the EDC is not functional. The interphalangeal joints of the fingers (index, long,
ring, and small) are extended by the intrinsic muscles of the hand, which are innervated by the median and ulnar nerves, and therefore are not affected by radial nerve palsy. Radial nerve–mediated sensation includes the dorsal surfaces of the forearm and hand; the most specific location for radial nerve sensation is the dorsum of the first web space on the hand.

Most radial nerve palsies are thought to be traction injuries (neurapraxias), as opposed to complete disruptions (neurotmesis) or impalings on bone edges [146]. Rarely, the radial nerve may become entrapped within the humeral fracture site, creating neurological deficits [118]. In the setting of high-velocity penetrating injury (gunshot wounds), a radial nerve palsy may be secondary to blast effect of the projectile (as opposed to nerve transaction). Radial nerve palsy at presentation of a patient with a humeral shaft fracture is not considered an indication for surgery, either for nerve exploration or humeral shaft fracture fixation. In the past, humeral shaft fracture patients presenting with intact radial nerve function which then is lost after manipulation of the fracture (e.g., for reduction) was considered an indication for operative nerve exploration; it has been shown, however, that the bulk of these “iatrogenic” radial nerve palsies resolve on their own, with no residual deficit, and that fracture fixation or nerve exploration is not indicated in these patients either [118]. Humeral shaft fracture fixation should be undertaken for patients who would benefit (or who specifically request fixation), after thorough risk and benefit discussions with the patients and/or their families, and should not be prompted by the presence of a radial nerve deficit. Electromyography and nerve conduction studies are not helpful in the acute setting, and have low sensitivity and specificity regarding the etiology of radial nerve palsy immediately after injury. Ultrasonic examination, however, can be beneficial to detect nerve laceration or entrapment, when utilized by experienced practitioners [148].

Although radial nerve palsies are most often transient, their recovery can take many weeks to months. During this time, flexion contractures of the wrist and digits can occur. Splinting and occupational therapy, with daily manual stretching exercises, are beneficial to minimize this problem. Electromyography and nerve conduction studies may be performed between 6 and 12 weeks following the onset of the radial nerve palsy if there has been absolutely no recovery of function after the injury [146]. Functional recovery is slow; rapid recovery should not be expected. A good rule of thumb is that nerve recovery progresses at approximately 1 mm per day [149]. Therefore, an injury to the radial nerve at the midshaft of the humerus should be expected to result in dorsal hand sensory deficits for many weeks.

Sciatic nerve palsies can occur in conjunction with pelvic or acetabular fractures. Acetabular fractures with posterior dislocation of the hip have
an association with the development of sciatic nerve palsy [150]. Pelvic or acetabular fractures, with extensions of fracture lines into the sciatic buttress at the greater sciatic notch, can result in direct laceration of the sciatic nerve; this pattern of fracture can also result in catastrophic hemorrhage due to laceration of the superior and/or inferior gluteal arteries. Pelvic ring disruptions, with wide displacement of the hemipelvis, can also cause sciatic nerve palsies or lumbosacral plexopathies [151], perhaps due either to avulsion of nerve roots or to neurapraxia [152,153]. Nerve roots may be lacerated in association with sacral fractures [154]. The peroneal division of the sciatic nerve is more commonly affected than the tibial division [155]; it has been postulated that this has to do with more points at which the peroneal nerves are tethered down the lower extremity than the tibial nerves.

The bulk of sciatic nerve palsies are also neurapraxias [152]. Prognosis of these, however, is poorer than that for radial nerve palsy, perhaps secondary to the long distance across which recovery must occur (the nerve bud must travel from the pelvis to at least the superior leg, where innervation of the peroneal muscles and ankle and toe dorsiflexors occurs) [155]. Electromyography and nerve conduction studies are useful for characterizing the injury, and many patients with mild injuries regain good function [156].

Scapulothoracic dissociation, likened to a closed forequarter amputation [157], occurs when the shoulder girdle and upper extremity are pulled away from the midline [158]. Prompt recognition of this injury complex is vital. Significant degrees of scapulothoracic dissociation can result in the rupture of subclavian or axillary vessels [157,159]. The injury complex can have devastating effects upon the neurological function of the upper extremity, due to the stretch of nerves or brachial plexus, or due to the avulsion of nerve roots from the cervical spine [157]. Degree of neurological injury and prognosis for recovery correlates with the location of vascular injury; more proximal vascular injury correlates with more severe neurological compromise and poorer prognosis [160]. Evidence of expanding hematoma within the axilla of a patient with such an injury should prompt emergent vascular surgical consultation. Careful attention to the vascular status of the distal upper extremity must be paid to any patient with a distracted clavicular fracture, a significantly displaced scapular fracture, or a clear increase in distance on anteroposterior chest radiograph between the thoracic spine and the medial border of the scapula, known as the scapular index [161]. CT is of questionable benefit for initial diagnosis, as the axis of the beam may not be perfectly perpendicular to the axial skeleton, and therefore determination of scapular index may be unreliable. Recovery of brachial plexus function after scapulothoracic dissociation is unreliable at best, especially after nerve root avulsion [159,160,162].

SUGGESTED READINGS

DEFINITION AND GENERAL CONSIDERATIONS

Patients with inappropriate or excessive exposure to thermal, chemical, electrical, or radioactive agents are burned. The degree of injury and depth of burn are proportional to the amount of energy delivered to the tissue and duration of exposure to the offending agent.

In 2015, approximately 450,000 burn-related injuries were reported in the United States, necessitating approximately 40,000 hospitalizations. The 2013 National Burn Repository Report from the American Burn Association found 3.3% of burn-related injuries were greater than 40% total body surface area (TBSA) [1].

All human tissue is susceptible to burn injury, although skin and aerodigestive tissues are commonly involved. The embryologically distinct epidermal and dermal layers of skin behave differently when burned. Ectodermally derived epidermis is vital for fluid management, pigmentation, and protective immunologic functions, but the epidermis has little structural integrity at seven cells thick. What the epidermis lacks in thickness it makes up for with its regenerative properties; the layer’s abundant stem cells heal isolated injury of this layer without scar. The dermis, in contrast, is derived from mesenchymal cells and forms abundant scar while healing. The dermis gives skin its strong mechanical integrity and as such is the focus of much of acute burn care [2].

Burn thickness may range from superficial epidermal involvement to char of the deepest bone. Accurate burn depth assessment is critical in the patient’s clinical management but remains a qualitative appraisal. Significant “bench to bedside” work has been performed using both laser Doppler and hyperspectral imaging to quantify tissue injury; however, clinical judgment remains the gold standard [3].
Burn depth occurs on a spectrum: superficial burns involve the thin epidermis only; partial-thickness or second-degree burns disrupt the epidermis’ basement membrane and encroach into the dermis, resulting in blisters; the dermis is burned in full-thickness or third-degree burns, which often look pale, ashen, and leathery. Fourth-degree burns involve the underlying fat, fascia, or bone. Third- and fourth-degree burns typically outstrip the body’s regenerative capacity and require operative excision of damaged tissues and restoration of skin integrity.

Because of the body’s inflammatory response to the initial traumatic insult, burn depth may change over time, colloquially described as “deepening.” Pink burned tissue with wheepy blisters on the day of presentation may progress to appear white and dry—a full-thickness injury—and much of acute burn care is directed toward preventing this conversion.

A burned patient is a trauma patient and should initially be evaluated in accordance with the systematic techniques of Advanced Trauma Life Support (ATLS) principles. Airway should be evaluated and secured when appropriate to facilitate breathing and ongoing oxygenation, followed by an evaluation of the patient’s circulation. Primary traumatic survey should encompass evidence of head injury, long bone trauma, and acute hemorrhage. Evaluation of the burned tissue is part of a prompt secondary survey.

Accurate information around the mechanism of burn and location (closed or open space) inform the clinician’s suspicion about concomitant injuries such as inhalational injury, deep muscle injury from electrocution or fractures from a high fall, and the like. The initial depth of the burn and TBSA affected should be documented in the medical record. Please see the section Inhalational Injury for further management of the burned airway.

TBSA can be calculated with the “rule of nines” and the Lund–Browder scales (useful for contiguous injury), whereas the palmar surface of the patient’s hand, representing 1% TBSA, is used as a guide in noncontiguous injuries [4]. TBSA should include only partial and full-thickness burns; superficial burns confined to the epidermis are not included in this calculation [5].

Overall morbidity and mortality are influenced by TBSA, patient’s age, medical comorbidities, and presence of inhalational injury. Burn patients with greater than 20% TBSA and those with inhalational injury are at risk for development of burn shock (see Burn Shock section). Age of the burned patient is of vital importance when predicting a patient’s mortality; with increasing age, risk of death is greater with lower total body burn surface area. The Baux Score is a combination of TBSA and age and is predictive of burn mortality for burns greater than 15% [6].

The patient’s predicted mortality rate rises to over 90% when the
patient is older than 60 years, TBSA burned is more than 40%, and the patient has an inhalational injury; when two factors are present, calculated mortality is roughly 33%. Death is usually caused in such cases by multisystem organ failure as a result of sepsis. Burn care before the 1980s focused on topical antibiotics and delayed excision and grafting. The clinical paradigm has shifted in the past 35 years to early surgery (within 5 days), and survival rates of major burns—in conjunction with advances in critical care—have dramatically improved [7]. Because of the interdisciplinary care required to take care of the burned patient, prompt transfer to certified burn centers in accordance with American Burn Association guidelines has been shown to have the best outcomes, especially in cases of inhalational burns [8].
BURN SHOCK

Burn shock is a form of vasodilatory shock, akin to the general term “systemic inflammatory response,” and creates a significant initial fluid volume resuscitation requirement for the burned patient. Large volume repletion is usually necessary only for patients with burns exceeding 20% TBSA and is essentially universal in larger surface area burns [9].

This fluid need comes from the body’s systemic response to burned tissue. Kinins, serotonin, histamine, prostaglandins, and oxygen radicals are the vasoactive mediators released in response to the burn injury and stimulate systemic vascular permeability. These mediators increases vascular permeability, with resultant decreased capillary oncotic pressure and subsequent severe total body edema, even in nonburned tissues. Albumin is functionally lost into the interstitium, thereby increasing extravascular oncotic pressure, compounding the edema [10].

The burned patient’s fluid “requirement” should be thought of as that volume needed to optimize organ function and tissue perfusion. Classically, this has been calculated with the Parkland formula using the patient’s TBSA burn and weight, times the coefficient of 4, with half the isotonic fluid given in the first 8 hours from injury and the second half given in the subsequent 16 hours. However, goal-directed therapy is the gold standard of care, aiming for a urine output of 0.5 to 1 mL/kg/h, and the calculated fluid requirements should serve only as a general guide for meeting this goal. If the patient’s urine output is greater than 1 mL/kg/h, the infusion rate should be decreased and titrated appropriately. If urine output remains high, urine electrolytes and glucose should be evaluated with specific attention to glycosuria secondary to the burn hypermetabolism.

Albumin is an increasingly popular component of the resuscitation of a burned elderly patient or in those whose fluid requirements in practice are significantly higher than their calculated needs [11]. Central venous access may be necessary to deliver the appropriate resuscitation in a timely manner and is ideally, but not essentially, placed through nonburned tissue [12].

The use of pressors requires clinical judgment and should be employed only in settings of persistent hypotension despite adequate fluid resuscitation with both crystalloid and colloid rescue therapy. For patients with persistent oliguria, preexisting renal failure, or congestive
heart failure, a pulmonary artery catheter or the equivalent measuring tool to quantify hemodynamics is advised \[13\].

Adrenal insufficiency should be suspected when hypotension persists despite solid volume repletion and adequate vasopressor therapy and is further suggested by concurrent hyponatremia and hyperkalemia. Although somewhat unusual, a high mortality exists when disturbances of the hypothalamic–pituitary–adrenal axis are found early in a patient’s burn shock course. A single blood cortisol of less than 15 \(\mu\)g per dL in a stressed patient is suggestive of adrenal insufficiency, although results of a corticotrophin stimulation test should not delay implementation of glucocorticoid replacement therapy in the face of circulatory collapse. In questionable cases, a corticotrophin stimulation test is confirmatory and not skewed by dexamethasone, which enhances vascular tone but does not have the mineral corticoid activity seen with hydrocortisone administration \[14\]. Glucocorticoids are known to unfavorably affect skin engraftment, although vitamin A supplementation seems to limit the wound-healing delay \[15\].

The pathophysiologic similarities between septic shock, systemic inflammatory response, and burn shock may have a common pathway that could be interrupted to improve outcomes. \(\beta\)-blockade, antihistamines, FFP, generous narcosis, nonsteroidal anti-inflammatory agents, and glucocorticosteroids are among the many approaches investigated to mitigate this cellular “hysteria.” None of these approaches have proven superiority in multicenter prospective trials to date \[16\].

In the acutely burned patient, central shunting of blood compensates for anhydremia, yet deprives peripherally injured tissue of vital perfusion. This low blood flow to skin keeps essential nutrients and gas exchange from partly burned tissue, resulting in conversion of partial-thickness injury to full-thickness tissue loss. Excessive fluid resuscitation, however, has the same result by compounding extravascular tissue edema \[10\].

The biologic basis of burn wound conversion, also called secondary burn progression, has not been fully elucidated. Direct cellular damage, inflammation, and ischemia are significant contributing factors. Investigations into erythropoietin derivatives and resolvins have shown preservation of microvascular network in animal models. This may allow prevention of secondary burn progression \[17\].

The gastrointestinal tract is an underutilized resuscitative venue. Enteral nutrition and resuscitation may begin on the day of injury with the caveat that patients in shock or requiring vasopressors can develop bowel ischemia and enteral feeds may increase the metabolic needs of the gut, contributing to bowel ischemia and necrosis. This risk can be minimized by initiating enteral rehydration and nutrition within 24 hours of the initial burn \[18\]. Patient’s not tolerating enteral feeds or those with
abdominal hypertension (see Chapter 52) should be given total parenteral nutrition.

Typically, by the third postburn day, the patient’s systemic inflammatory response has dampened and vascular integrity is returning, with decreased fluid requirements. After this point, it is reasonable to limit fluid replacement to maintenance levels and allow the patient to autodiurese or judiciously use diuretics in the elderly or cardiac-compromised patient [9].
CARDIOVASCULAR RESPONSE

Unresuscitated burn victims die of hypovolemic shock. An untreated victim would show progressively decreasing preload and cardiac output. Unfortunately, during the initial 4-to-24-hour postinjury period, even “adequate” volume repletion will not maintain baseline cardiac output, and decreased cardiac contractility and diastolic dysfunction prevail. This decrease in contractility is more pronounced among those with an inhalational injury and is related to both increased pulmonary vascular resistance and increased systemic nitric oxide production. This temporary and seemingly maladaptive cardiac dysfunction improves as time elapses from the initial injury and is followed by tachycardia, which is often maintained for weeks after burn [19,20].

Given this hyperdynamic response, the elderly and patients with preinjury cardiac compromise are more susceptible to heart failure in this period. Laboratory workup may reveal elevations in cardiac enzymes, including both creatine phosphokinase (CPK) and troponin-I, and although myocardium may be at risk, the evaluation of elevated cardiac labs in burn shock patients goes beyond a single lab value. Elevated troponins should not be used as an indication for emergent cardiac catheterization without other signs or symptoms of acute cardiac ischemia, such as electrocardiogram changes [19].
INHALATIONAL INJURY

An inhalational injury occurs when toxic combustants have been inhaled, causing a systemic inflammatory response and local injury in the bronchial pulmonary tree. History of fire or explosion in a closed space and findings of singed facial structures, carbonaceous sputum, and respiratory distress often corroborate the diagnosis. Approximately 3.5% of adult burn admissions have inhalational injury, which increases mortality rate for like burn size; however, larger burns have an incidence of inhalational injury closer to 15% [1]. Concurrent inhalational injury intensifies burn shock and may require up to 50% more fluid for adequate resuscitation. This component of the inhalational injury cascade appears to be driven by the sensory neuronal pathway, because the response can be truncated by sympathetic blockade in experimental animal models [21].

Clinically, in the acutely burned patient with an inhalational injury, airway management is paramount. The clinician should look for signs of upper airway obstruction secondary to edema, which often develops hours after initial injury. Stridorous patients should be intubated urgently; preferably with an 8-Fr endotracheal tube to allow for bronchoscopy and removal of respiratory tract secretions. Currently, no scale of severity for inhalational injury is used clinically. Bronchoscopy is most useful to characterize the presence or absence of tracheobronchial inflammation and provide therapeutic pulmonary lavage [22].

Immediate threats include carbon monoxide (CO) poisoning and cyanide (CN\(^-\)) toxicity. Generally, the lethal level is >60% COHgb. Breathing 100% oxygen by mask or endotracheal tubes should bring the half-life of COHgb to about 60 minutes [23]. CN\(^-\) poisoning causes cytochrome oxidase inhibition and loss of hypoxic pulmonary vasoconstriction, increasing lung dead space. CN\(^-\) is lethal in levels over 1 \(\mu\)g per mL, while 0.02 \(\mu\)g per mL occurs in healthy nonsmokers. For practical purposes, a normal COHgb rules out CN\(^-\) toxicity [23].

Inhalational injury has multiple sequelae, including endobronchial and interstitial edema, alveolar damage, mucociliary dysfunction, endobronchial slough with cast formation, functional pulmonary shunting, and decreased lung compliance. Increased bronchial blood flow causes increased interstitial edema. Bronchial epithelium sloughs and
combines with exudates and fibrin to form “plugs” that nurture bacterial growth and create mechanical airway obstructions. Aerosolized heparin in conjunction with N-acetyl-cysteine may prevent cast formation and has been shown to decrease lung injury scores and ventilator days and has been especially helpful for pediatric patients where narrow airways easily obstruct [24,25].

Although burn patients are at increased risk for pneumonia because of their immunocompromised state, immobility, and inability to clear secretions, prophylactic antibiotics are not recommended. Pneumonia and tracheobronchitis should be treated by culture-directed therapy, using Gram stain, culture of sputum, or bronchoscopy specimens and incorporate a hospital’s known bacterial sensitivities [26]. Aspiration risks should be minimized, and lung protective ventilator settings should be used. Patients’ overall condition and pulmonary performance by way of usual weaning parameters dictate extubation time [27]. The risk of upper airway obstruction before extubation should be assessed by deflating the balloon and audible appreciation of air leak. If no air leak is present, extubation should not be performed.
METABOLIC AND NUTRITIONAL CONSIDERATIONS

The insensible fluid and protein losses from burn wounds are extraordinary. Protein catabolism, compounded by losses through the wound bed and the interstitium, results in severe hypoproteinemia, and the hypermetabolic response that occurs after a thermal injury is more than that observed after most other forms of trauma or sepsis. The loss of regulated vasomotor tone, possibly in an effort to provide maximal nutrient delivery and gas exchange to the wounded tissues, results in significant evaporative heat loss. Hypothermia from weeping wounds and dwindling energy supplies from the catabolic, muscle-wasting condition of burn shock is easily avoided with external warming. The ambient temperature in the patient’s room should be kept warm, 90°F to 100°F, in an effort to shunt calories away from being used in thermostasis.

Muscle wasting, a difficult complication of the hypermetabolism associated with burn wounds, can be ameliorated through anabolic enhancement. The two most common approaches are recombinant human growth hormone (HGH) and oxandrolone. HGH is associated with hyperglycemia requiring insulin support and has largely been supplanted by oxandrolone, which must be given enterally at 0.2 mg/kg/d (max dose 20 mg) divided twice daily, thereby limiting its use in patients with ileus [28,29].

The patient with a major thermal injury has a metabolism characterized by increased muscle proteolysis, lipolysis, and gluconeogenesis. Burn wounds use glucose in greatly increased quantities. Hyperglycemia is common with burn catabolism, may exacerbate muscle wasting, and should be tightly controlled with insulin. Nitrogen loss should also be supplemented to combat muscle wasting and to enhance the immune system [30].

Burn patients need two to three times their basal energy expenditure in calories [30]. Significant burn injuries require 2 g per kg protein, glucose should contribute 50% to 60% of the calories, and the calorie-to-nitrogen ratio should approach 150:1. All attempts should be made to feed the patient enterally, and, ideally, enteral nutrition should be initiated within 24 hours of admission. Prompt enteral feeding has been shown to decrease patient’s length of hospital stay as well as burn wound infection and is thought to maintain the integrity of the gastrointestinal track [14]. In addition to early enteral nutrition, supplementation with trace elements such as copper, zinc, and selenium is also important for helping decrease infectious complications [31].
BURN WOUND SEPSIS

Burn victims develop multiple defects in their immune system both mechanical and immunologic that predispose them to an increased risk of infection. Topical antimicrobials (e.g., silver sulfadiazine or mafenide acetate) in the context of good overall wound care help decrease the incidence of frank burn wound infections. However, primary treatment of infected burns remains surgical excision and tissue coverage with autograft or skin substitute (see “Early Excision and Grafting”).

The signs of burn wound sepsis typically present as a greenish gray discoloration of the burn, purulent fluid from the wound, and eschar separation along with cellulitis in the surrounding unburned skin. If not treated at the earliest possible time, systemic sepsis will ensue. Diagnosis can be confirmed by biopsy of the wound with quantitative culture but should not preclude total and urgent excision [32]. Systemic antibiotics are started if florid infection is suspected and tailored or stopped once burn biopsies for quantitative bacterial counts and blood culture results are obtained.

The overall hypermetabolic state associated with severe burns can have significant effects on the pharmacokinetics and pharmacodynamics of many medications including anti-infectives. As one example, Mafenide acetate penetrates eschar and is most effective against Gram-negative organisms; however, Mafenide acetate is known to cause metabolic acidosis as a carbonic anhydrase inhibitor and may select for fungal overgrowth [26].

Immunity and Infection

Significant burn injury that induces a systemic inflammatory response may also induce a compensatory anti-inflammatory response syndrome. This combination can lead to persistent inflammation-immunosuppression catabolism syndrome. As such, large surface area burn patients are at high risk for infection, which is often the precipitating cause of late deaths [33]. The pulmonary tree and the burn wound beds themselves are the most common sites and foci for fatal infection. Early wound infections, within 10 days of injury, are typically Gram-positive organisms. Later, pseudomonas is a common and potentially lethal organism, although fungal infections may occur in the subacute period and are often ominous. Central lines and urinary catheters should also be evaluated as possible infectious nidi. A growing and considerable body of evidence links bacterial translocation from the gut as a source of unexplained bacteremia [26]. Presence of gut bacteria
and endotoxin in the lymphatic system supports this theory [20]. This risk may be decreased by enteral feedings and supplementation with glutamine. Immunoenhancing regimens are an area of intense study [34].
SURGICAL CONSIDERATIONS

Early Excision and Grafting

By the 1980s, the operative paradigm had shifted toward early (within 5 days) excision of full-thickness burns to limit the inflammatory forces driving “burn shock.” In the operating room, excision of full-thickness burns is performed to the level of healthy bleeding tissue. Blood loss of 0.5 mL of blood per kilogram of patient weight for every percentage of TBSA excised is routine.

Once an area has been grafted with autologous tissue, shear forces must be minimized because the grafted skin initially lives by diffusion of nutrients from the underlying wound bed and imbibition until inosculcation and neovascularization can take place. The use of negative pressure wound therapy devices (NPWT) as protective dressings from graft-killing shear has become the standard of care [35].

In areas of mixed partial- and full-thickness burns, excision of partial-thickness burns in addition to full-thickness burns may be necessary in order to facilitate practical skin grafting. Using a combination of autografts on completely excised burns and xenografts on partial-thickness burns is also a means to facilitate timely healing. Xenografts will function as a biologic dressing, decrease insensible fluid loss, and do not need frequent dressing changes, allowing the newly applied autografts to inosculate and neovascularize unmolested.

Escharotomies

Burned tissue has significantly less compliance than normal unburned tissue and may acutely restrict breathing as well as blood flow to the extremities. In the initial evaluation period, it is important to evaluate respiratory status as well as peripheral perfusion. Poor oxygenation can be a sign of frankly restrictive respiratory physiology secondary to a burned torso, and acute limb ischemia can also develop from a badly burned limb. The treatment for both of these conditions is immediate escharotomy at the affected site. Torso escharatomies will improve excursion of the chest wall, and limb escharatomies alleviate the functional venous tourniquet of a significant burn, equivalent to a fasciotomy for acute compartment syndrome. On the torso, escharotomy
incisions are made along the anterior axillary line and connect at the level of the second rib and the xyphoid. In the extremities, incisions are made along the medial and lateral aspects of the appendage. In rare situations, orbital pressures can be elevated secondary to retro-orbital edema, necessitating lateral canthotomies.

**Abdominal Compartment Syndrome**

The inflammatory cascade and changing oncotic pressures in a patient with an acute burn undergoing resuscitation can lead to abdominal compartment syndrome. Abdominal hypertension is typically first identified by decreased urine output and restrictive airway dynamics. Transurethral bladder pressures in a chemically paralyzed patient greater than 20 cm H₂O are considered diagnostic for abdominal hypertension. Failure to identify and treat abdominal compartment syndrome can have devastating consequences including renal and respiratory failure as well as abdominal organ ischemia secondary to abdominal vasculature compression. Definitive treatment is decompressive laparotomy [36]. Please see Chapter 52 for a detailed discussion of abdominal compartment syndrome.
SPECIFIC INJURIES

Electrical Injury

The magnitude of electrical injuries varies depending on the voltage of current delivered to human tissue. Low-voltage (less than 1,000 V) injuries create thermal burns, injuring tissue from the outside in, whereas high voltage (greater than 1,000 V) can initially be deceiving in their devastation because a significant portion of the injury is not cutaneous but rather to the underlying muscle and bone. Very high-voltage injuries will have both extensive deep tissue injury and obvious cutaneous injury [37].

Immediate life-threatening conditions related to electrical injuries include cardiac dysrhythmias and spinal cord injury, either from direct injury, fall, or because of tetany resulting in spinal column fracture and cord injury.

Exit and entry wounds should be identified when possible, because this will help identify potentially affected tissue. Compartment syndrome from myonecrosis is common, especially in the upper extremity, and patients should be monitored closely for this complication in the first 24 hours. Limbs injured by electricity with resultant compartment syndrome require fasciotomies rather than simple escharotomies [38].

Aggressive fluid resuscitation should be initiated quickly to limit the renal effects of myonecrosis and myoglobinuria. Maintaining high urine output can help prevent kidney injury associated with myoglobin crystallization in the renal tubules. Daily monitoring of CPK may be beneficial in identifying potential or ongoing muscle necrosis. Persistently high levels may indicate muscle necrosis and need for surgical debridement [39].

Chemical Injury

Acids and alkali bases injure tissues by different mechanisms. Alkali bases burn tissue by liquefactive necrosis of subcutaneous fat, thrombosing perfusing vessels. Acids in turn burn by coagulation necrosis and as such are typically more superficial in their penetration of tissue [40]. Hydrofluoric acid (HF) burns are unique, however, because HF is a strong calcium and magnesium chelator. This can lead to devastating cardiac dysrhythmias and cardiac arrest owing to severe hypocalcemia. Topical calcium gluconate slurries are a mainstay of treatment for HF burns. Systemically, intravenous calcium gluconate is frequently necessary, and intra-arterial infusions have been effective for
pain relief and preservation of tissue in extremity burns caused by HF [41].
Beyond the physiologic stress induced by burns, the burned patient undergoes significant psychological stress. Posttraumatic stress disorder (PTSD) has been reported in up to 45% of burn patients [42], and previous psychiatric history has been shown to be a risk factor for PTSD in the broadly studied burn population. Self-immolation accounts for only 4% of burn admission; however, these patients present complex patient care problems, because there is typically significant psychopathology that may hinder recovery [43].

Adequate pain control during their hospitalizations and during dressing changes has been shown to limit the long-term psychiatric effects of burn trauma [44]. Opiates, benzodiazepines, and the full range of dissociative medications are indicated. Unlike other critically ill patients, “sedation holidays” are not commonly used because these breaks in regular analgesia can create undue physiologic and psychological stress for the patient, increase catabolism, cardiovascular stress, and risk for development of PTSD [45]. Once the burn has been treated, wounds closed, and shock resolved, tapering of sedatives and narcotics can be initiated such that the patient may be weaned from the ventilator and avoid withdrawal symptoms. Among patients with extremity burns, long-acting regional anesthetics may be beneficial for pain control and permit better burn care and therapy.

SURGICAL PROBLEMS IN THE INTENSIVE CARE UNIT

MITCHELL CAHAN
The modern intensive care unit (ICU) is teeming with technology; however, it is probably the most stressful place in the hospital [1]. Advanced technology has brought sophisticated instrumentation and databases to the bedside [2]. Entirely new therapies are possible for grave diseases, such as low tidal volume strategies for acute lung injury or early antimicrobial therapy for sepsis [3–5]. Increasing sophistication of care leads invariably to increased complexity. This complexity poses opportunities and potential hazards [2]. Patient turnover is rapid and survival rates continue to improve. Many caregivers are involved, and all of them expect some input into the process of care. Meanwhile, a designated credentialed provider always must be responsible for the overall care plan and occasionally adjudicate differences of opinion regarding difficult decisions, or reconcile conflicting recommendations from key team members. The conflicts arise not only from uncertainties about outcomes but also about what is understood as success. In the clinical world, success is defined as survival to leave the ICU; however, in the moral world of families and friends, success often means a patient returning to an independent life with resumption of normal activities. Effective care of patients requires that all parties involved understand each other’s point of view.

DEFINITION OF ICU MODELS AND LEVELS
The open ICU model is an ICU in which patients are admitted under the care of an internist, family physician, surgeon, or other primary attending of record, with intensivists often available providing expertise via elective consultation [6].

Intensivist co-management is an open ICU model in which all patients receive mandatory consultation from an intensivist. The internist, family physician, or surgeon is the co-attending of record with intensivists collaborating in the management of all ICU patients.

In a closed ICU model, patients admitted to the unit are transferred to the care of an intensivist assigned to the ICU on a full-time basis. Patients are accepted to the ICU only after approval by the intensivist. For periods ranging from 1 week to 1 month at a time, the intensivist's clinical duties consist of caring for patients in the ICU, with no other clinical responsibilities.

A mixed ICU model may consist of directorship and daily ICU rounds by the intensivist (closed unit and/or co-management), or simply the presence of a full-time intensivist in the ICU (including examples of all three models).

The American College of Critical Care Medicine has described three levels of hospital-based critical care centers to optimally match services and personnel with community needs [7]:

1. Level I critical care centers have ICUs that provide comprehensive care for a wide range of disorders requiring intensive care. They require the continuous availability of sophisticated equipment, specialized nurses, and physicians with critical care training.

2. Level II critical care centers have the capability to provide comprehensive critical care, but may not have resources to care for specific populations (e.g., cardiothoracic surgery, neurosurgery, trauma).

3. Level III critical care centers may provide initial stabilization of critically ill patients but are limited in their ability to provide comprehensive critical care.
COMMUNICATION AMONG ICU TEAM MEMBERS

Interprofessional tensions can threaten the delivery of quality health care in the hospital setting. Such tensions have been documented at several clinical locations including the ICU [8]. The ICU in particular is a nexus for interspeciality tensions because of its unique role in the care of the hospital’s most critically ill patients and associated management of critical care resources [9]. Conflict in the ICU is frequent; more than 70% of ICU clinicians report experiencing conflict weekly [10,11]. The combination of caring for acutely ill patients, end-of-life decision-making, and coordination of large interprofessional teams can lead to frustration, communication breakdown, and discord among members of the health care team. The epidemiology of this conflict has been very well described in the Conflicus study [10]. Conflict has been associated with lower quality patient care [12,13], higher rates of serious medical errors [14], staff burn out [15,16], and greater direct and indirect costs of care [17]. ICU conflict can occur between the health care team and patients’ families, among members of the ICU team, and among different groups of clinicians caring for the same patient, most notably between surgeons and intensivists.

Lingard et al. [9] studied the forces governing the interactions among professions (nurses and physicians) and specialties (ICU team and consultants). This group found out that the level of collaboration or conflict within the ICU team and between ICU and other specialties fluctuated on the basis of six important catalysts: authority, education, patient needs, knowledge, resources, and time. Two dominant mechanisms were also described and categorized in their analysis as “the perception of ownership” and the “process of trade.”

Ownership was perceived as both collective (ICU team) and individual [9]. It promoted collaboration between members of the ICU team and was often established by contrast with those outside of the core team such as surgeons, internists, or nurses from the wards. Individual ownership is also a dominant issue and includes instances where members recognized their own or other’s skill; this recognition is part of the smooth collaborative functioning of the team.

Within the process of trade, team members traded valued commodities
including equipment, resources, respect, goodwill, and knowledge as they negotiated their collaborative work [9].

The forces of ownership and trade have a central role in the daily negotiations that constitute teamwork in the ICU setting. When ownership is not attended to, or one commodity is not offered in trade for another, tensions accumulate and collaboration is compromised [9].

**The Surgeon’s Perspective**

The qualities that define a surgical personality have been described by anthropologist Joan Cassell [18] as decisiveness, control, confidence, and certitude. The surgeon often views his or her relationship with the patient as a covenant to cure. Actions that threaten this covenant as relinquishing responsibility for the care of a patient to another practitioner, losing control over key decisions, and proposals toward comfort with the expectation of death can be strongly rejected by the admitting surgeon [44]. This ownership searching for an ideal outcome is valuable in that the patient has a strong advocate to facilitate recovery; however, surgical obstinacy with respect to sharing responsibility for care and resulting reluctance to direct efforts toward comfort can deny the dying patient both dignity and control [19]. Surgeons are affected by the increasing demands of clinical practice, spending more time in the office and in the operating room, at the cost of less available time to see and manage patients in the ICU.

Olson et al. reported in a study on conflict of postoperative goals of care that 40% of surgeons who routinely perform high-risk operations reported conflict with critical care physicians and nurses regarding the goals of care for their patients with poor postoperative outcomes [20]. Surgeons who reported higher rates of conflict had fewer years in practice and worked in an academic setting. Surgeons with more experience may be more accepting and may have developed coping strategies for unwanted outcomes. Additionally, surgeons who practice in a closed ICU reported higher rates of conflict about goals of care.

**The Intensivist’s Perspective**

In contrast to the surgeon’s perspective, the intensivist’s point of view is often more focused on symptom relief and comfort. This different perspective does not mean that intensivists are any less goal oriented than surgeons; intensivists actually embrace goal-directed care [19].

From the surgeon’s perspective, persistence in the face of overwhelming odds is seen as a noble obligation. From the intensivist’s perspective, persistence in the face of overwhelming odds can be costly, painful, and disrespectful if the patient has expressed any wish to avoid heroic measures.
The effectiveness of a dedicated intensivist caring for ICU patients has been shown in multiple reviews [21]. The presence and participation of an intensivist-directed team can identify and treat problems before catastrophic complications occur. Understanding of sepsis, mechanical ventilatory support for acute respiratory distress syndrome (ARDS), and description and treatment of endocrine dysfunction among the critically ill have led to protocol-driven care and improved survival [22,23].

Young and Birkmeyer [24] have provided estimates of the relative reduction of annual ICU mortality resulting from conversion of all urban ICUs to an intensivist model of management. Assuming an ICU mortality of 12% and estimating that 85% of urban ICUs are not currently intensivist managed, they calculated that there are approximately 360,000 preventable deaths annually in U.S. urban ICUs that lack intensivists. A conservative projection of a 15% relative reduction in mortality resulting from intensivist-managed ICUs yields a predicted annual saving of nearly 54,000 lives.

The ICU Nurse’s Perspective

The ICU nurse has a fundamental role for supporting and comforting ICU patients and their families. Nurses spend the most time with ICU patients and family members and thus are a valuable resource for identifying the patient and family understanding and evaluating the effectiveness of communication. Moreover, nurses act as the medical intermediary for families, as well as the link between health care providers, particularly when surgeons and ICU physicians disagree [18,25,26].
Consensus is a process-based concept that is a core element of high-performing teams. It allows essential communication that enables teams to effectively perform high-fidelity tasks. Consensus is founded on assent of the team members and sometimes requires vetting, discussion, and even negotiation. Establishing a process by which consensus is consistently achieved is an important skill for ICU team leaders. Consensus is a state of acquiescence to team-based decisions that does not require that all team members are in full agreement with all of the details of a decision, rather that all key members assent to the critical concepts of the decision [27]. In the context of patient care, it is better to maintain a state of consensus than to attempt to build it after disagreement has festered [28]. A summary of helpful communication strategies is presented in Table 47.1.

</table>
One effective approach to build and maintain consensus is including key team members in an interprofessional rounding process [29]. In this context, “including” means listening and valuing input from all stakeholders and on occasion soliciting the opinions of those who may not be in consensus with the plan of care. Including key personnel like the surgeon [30] on interdisciplinary rounds is one of the best methods for managing the consensus-building process [31,32]. An increasing number of ICU teams have found that including the patient and family members on bedside rounds [33–35] is helpful for preventing and resolving differences of opinion regarding the patient’s goals for minimal functional outcomes [36,37]. This approach has the advantage of removing the nurse or intensivist from the messenger role and allowing a more balanced discussion of the merits of alternative goals for the care plan. Establishing clear patient-centered goals is often helpful for achieving consensus on specific care plan elements and increasing the comfort of reluctant team members to assent to a comfort-oriented care plan [38].

The process of avoiding confrontational and emotion-laden open or hidden disagreements involves active listening skills and the thoughtful inclusion of consultants, review of medical advanced testing and imaging, and inclusion of the patient or their medical decision maker in team discussions. The most important consensus-building skill for an ICU team leader is to value the dissenting opinions of team members, particularly those of the operating surgeon and nursing staff. Adaptation of the patient-focused V.A.L.U.E. system that was developed at the University of Washington for difficult communication can also be helpful in the context of team communication [39]. In this context, “V” is for valuing comments made by dissenting team members, “A” is for acknowledging the emotions associated with their point of view, “L” is for actively listening, “U” is for understanding the dissenters as individuals, and “E” is for eliciting their comments by creating safe space for their expression. This approach can be highly effective when routinely employed, and team members learn to present their opinions efficiently. One key concept is a proactive ICU team approach that prepares for
managing potential compromised critical care functional outcomes before they have occurred.

Proactive management starts by identifying gaps between the patient or surgeon’s goals for functional outcomes and those that are likely to be achieved. The identification of the gap in expectations can be managed in several ways and all start with achieving agreement on the medical facts [38,39]. When the medical facts are not clear, consultants, pathologic evaluation of tissue specimens, advanced laboratory studies, and radiologic testing can be helpful for achieving consensus regarding the diagnosis and for defining practically achievable alternative therapeutic approaches. Establishing the medical facts and options allows the team to discuss alternative care plans and the metrics by which their success or failure can be judged.

Team consensus, including that of the operating surgeon, on a specific approach allows implementation of a time-limited plan of aggressive care. Including “clinical milestones” or objective metrics by which the success or failure of the plan will be judged allows presentation of the plan to the patient and medical decision-makers with a date for a “difficult discussion” should the care plan not achieve the clinical milestones [38]. This approach has been shown to improve outcomes and support patient-defined values because it encourages team members that favor a comfort-only approach to contribute fully to an aggressive care trial and those who favor aggressive care to transition to a comfort-oriented approach [40]. Time-limited trials of aggressive care that use clinical milestones that medical decision-makers can easily identify have the advantage that ICU team members spend less time explaining unpleasant information and are better able to advocate for comfort and dignity at the end of life. This approach also supports physiologically improving patients because prescheduled communication events can be used to discuss preparation for the process of physical and emotional rehabilitation after severe critical illness when continued aggressive care leads to improvement.

The adoption of collaborative interprofessional teams that are led by critical care professionals who adopt a proactive approach that is supported by V.A.L.U.E.-based communication will only rarely require the services of an ethics consultant [41] or a palliative care specialist [42] to heal broken-down communication or to work on resolving refractory value-based differences among interprofessional team members or between the ICU team and the patient or medical decision maker.
SUMMARY

The structure of the ICU can pose a barrier to the continuity of the surgeon–patient relationship and contributes to conflict when the surgeon is replaced as the primary decision maker for his or her patients by an intensivist [12,19,20,43]. Clearly, some of the ICU models described earlier can promote conflict with juxtaposition of clinicians with unmanaged competing interests. This is where valuing the input of the surgeon can have the greatest impact by ensuring that his or her patients receive an adequate trial of aggressive care. The surgeon who communicates his or her wishes and participates in patient-focused discussions of alternative approaches is a valued ICU team member and patient advocate [19].

Conflict is a significant public health problem that diminishes quality of care for critically ill patients. Consequences of conflict underscores the importance of surgeon–patient preoperative discussion of goals and values to guide postoperative decisions in the event of an undesired outcome [20,44–46]. In the absence of cooperation, conflict can affect patients and families, leading to decreased satisfaction with care and increased stress [10,13,47].

It is time to move from the rhetoric of team collaboration, toward a more clear understanding of the skills required to function in the competitive setting of the interprofessional health care team. These findings have educational implications for both trainees and practicing intensivists. As a result, medical schools have adapted by requiring competence in domains such as communication and collaboration within the medical team [48].

Communication is the most important factor for the intensivist who ensures that adverse events are reported in a timely fashion, that important decisions are discussed, and that the surgeon is included in the process. The surgeon should be willing to discuss rather than dictate and consider different approaches [19]. Clinicians from all backgrounds should focus on streamlining communication to allow energies to be spent more productively on better care for our critically ill postoperative patients [20].

Further research, particularly into ideal communication among surgeons, intensivists, and ICU nurses, is needed.

INTRODUCTION

Surgical infections present challenges of diagnosis and management in the intensive care setting. Manifestations may vary from simple superficial surgical site infection to complex generalized infections of the abdominal cavity. Abdominal infections are the third most common cause of sepsis in the intensive care unit (ICU) [1] and have been associated with high morbidity and mortality rates [2]. Rarely do surgical infections present as the sole reason for admission to ICUs. Patients who develop surgical site infections may have multiple comorbidities, be hemodynamically unstable, or even septic with concurrent failure of one or more organ systems, and are at high risk of treatment failure [3]. Early recognition and appropriate treatment is crucial in order to mitigate and control a potentially lethal infection.
PATHOGENESIS

Etiology of Surgical Infections

Surgical infections in the ICU population represent a complex clinical entity with a number of etiologic and contributory factors. This can be seen as a result of an inability of the host to adequately respond to a high number of pathogens of varying virulence. Patient-associated factors therefore play a significant role, including: malnutrition, as manifested by a low serum albumin concentration; older age; obesity; smoking; diabetes mellitus; localized malperfusion caused by vascular disease or a history of radiation to the site; and generalized malperfusion caused by peri- or intraoperative shock [4,5]. In addition, inadequate surgical technique, prolonged procedure time, or breaks in sterile technique may cause or contribute to the development of a surgical infection. Foreign body presence in the surgical field may help organisms to fester, as the number of bacteria required to cause a clinically significant infection may be lower in the presence of such a nidus [4]. In addition to skin flora as the source of causative organisms, surgical infections can be caused by spillage of enteric content or anastomotic leaks. Blunt abdominal trauma can also lead to perforation of the intestine or simple translocation of bacteria into the peritoneal cavity in the setting of intestinal wall hematoma or ischemia [6]. In an immunocompromised patient, this abdominal seeding may lead to peritonitis and infection, similar to a deep-organ space surgical site infection.

Abscess Formation

Abscess formation may occur when the patient’s immune systems attempts to locally control a certain disease process, such as free entry of pathogenic organisms into the abdominal cavity via perforation, surgical intervention, or trauma. Intraabdominal abscesses are confined to a part of the abdomen without free access to the peritoneal cavity. Especially in sizable abscesses, free diffusion of antibiotics and host immune cells into its center is usually not possible. This makes it almost impossible to control a sizable lesion with antiinfective therapy alone. Drainage via either the radiologic or open surgical technique is usually required to prevent hematogenous spreading of pathogens or rupture of the abscess into the peritoneal cavity. Abscess formation may occur at any location of
the body, including sites of venipunctures, chronic wounds or ulcers, and around indwelling catheters, and is a frequently observed intraabdominal process in postoperative critical care patients.

**Peritonitis**

Peritonitis is a generalized inflammatory reaction that may involve the partial or entire peritoneal cavity. It can be classified as primary, secondary, or tertiary peritonitis. The extent of peritoneal reaction may be dependent on the exact intestinal origin of the causative organism [7].

**Primary Peritonitis**

Infection of the peritoneum without obvious source or localized infection within the abdominal cavity is classified as primary peritonitis [8]. Obvious disruption of the gastrointestinal (GI) tract’s anatomic barrier is absent. Primary peritonitis tends to be a community-acquired disease of patients with previously existing ascites due to cirrhotic liver disease. A single causative organism can usually be isolated. GI flora such as enterococci and gram-negative bacilli tend to be responsible [9]. Other causes of primary peritonitis include infection of an indwelling peritoneal dialysis catheter, as well as rare cases of primary peritonitis in otherwise healthy patients, primarily caused by group A streptococcus [10,11]. The latter presentation can be associated with toxic shock syndrome [12]. In postoperative patients in an intensive care setting, primary peritonitis is a very rare occurrence.

**Secondary Peritonitis**

Peritonitis in the setting of perforation of a hollow viscus is called secondary peritonitis. Gross spillage of GI flora into the peritoneal cavity follows this disruption of the anatomic barrier. Causes include inflammation, malignancy, anastomotic leak, necrosis, fistula, and blunt and/or penetrating trauma. Secondary peritonitis is a frequently encountered problem in surgical intensive care patients. Reported mortality rates associated with secondary peritonitis range from 15% to 23%; however, this may increase in the setting of simultaneous sepsis or shock, as well as comorbid disease processes [13–15]. When isolation of microbial pathogens is successful, cultures are usually polymicrobial [16]. Outcomes from secondary peritonitis are dependent on adequate and timely treatment, source control, and the patient’s immune system [17].

**Tertiary Peritonitis**
Persistent peritonitis in the setting of exhaustive medical and interventional management is conventionally referred to as tertiary peritonitis [18]. The range of patients who progress from secondary to tertiary peritonitis can be as high as 20% [19]. It is however important to differentiate tertiary peritonitis from ongoing secondary peritonitis in the setting of inadequate source control, in the sense of failure to drain or evacuate existing abscesses or nidi of infection.

Tertiary peritonitis has been associated with a high incidence of nosocomial, multidrug-resistant organisms as well as immunologic dysfunction and altered endocrine stress response [20]. Different disease processes seem to be more or less prone to progress to tertiary peritonitis; for example, necrotizing pancreatitis has been associated with a high progression rate [19]. Tertiary peritonitis is linked to higher mortality, longer ICU stay, and more severe stage of end-organ impairment [21,22]. In a retrospective observational study with 92 cases of tertiary peritonitis, Evans et al. [23] could not correlate tertiary peritonitis as a sole prognostic factor of death after adjusting for other variables. Rather than being the cause of a patient’s death, tertiary peritonitis may in fact be a symptom of a highly dysfunctional host response to inflammatory stress.
PATHOGENS

The spectrum of causative pathogens in surgical infections is broad and depends on the underlying site of the primary disease as well as the clinical course of the patient. Community-acquired diseases that lead to surgical postoperative infections often start with an obstructive disease pattern and eventually become superinfected by GI flora; classic examples include acute calculous cholecystitis or appendicitis. The causative pathogens vary depending on the area of perforation. De Ruiter et al. [7] analyzed peritoneal fluid of 221 patients with abdominal sepsis due to perforated viscus at the time of the primary operation. They most commonly observed aerobic and gram-negative bacteria in appendiceal and colonic perforations; gram-positive bacteria were encountered with colorectal disease. Gastroduodenal perforations were associated with Candida species, most commonly *Candida albicans*.

Nosocomial infections are different for a variety of reasons. Pathogens tend to be less susceptible to antibiotic regimens and may be multiresistant [24]. In addition to this, the patient’s host response may be impaired or their GI flora may have been altered in the setting of prior antibiotic treatments, including potential overpopulation of virulent, ICU-acquired organisms. An increased risk of infection and subsequent multiorgan failure is observed among patients who are colonized with pathogens such as Candida species, *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, and *Enterococcus faecalis* [24,25].

Enterococcus is frequently isolated from patients with nonappendiceal peritonitis and is associated with the pathogenesis of many surgical abdominal infections [26,27]. Its involvement has been directly correlated with the severity of disease in the setting of anastomotic leakage [28]. However, antibiotic coverage of Enterococcus is not always indicated. Increasingly drug-resistant strains of Enterococci have emerged over the recent past and presented an increasingly difficult challenge. In particular, a growing population of vancomycin-resistant enterococci is feared, as this may lead to subsequent evolvement of vancomycin-resistant *Staphylococcus aureus* through genetic exchange among species.

Another challenge of surgical site infections is that caused by fungal pathogens. Fungal organisms benefit from decreased selection pressure from bacteria, especially after multiple courses of broad-spectrum
antibiotics, and have been associated with the development of tertiary peritonitis [29,30]. High mortality has been associated with intraabdominal candidiasis infection, especially in an ICU setting [31]. Unfortunately, even adequate treatment of Candida species has not always been associated with improved outcomes [32]. It is not clear whether Candida spp. isolated from abdominal sources are true causative pathogens or rather a symptom of poor host immune response and severity of underlying disease.
DIAGNOSIS

Clinical Examination

Suspicion for a surgical site infection can be raised by clinical examination. Erythema, drainage, or dehiscence are the first signs of a superficial infection, and may necessitate opening the incision at least partially in order to ensure adequate drainage. Gentle probing of the underlying fascia can help for assessment of the depth of infection and differentiating fascial dehiscence due to an infectious process from a possible enterocutaneous fistula.

Deep-organ space infections can also become clinically apparent. Rebound and guarding on exam, as well as inappropriate tenderness to palpation, can be signs of peritonitis or intraabdominal abscesses. It is important to realize that clinical examination findings can however be obscured by coexisting diseases, altered level of consciousness, the patient’s overall clinical deterioration, and the presence of sedating or paralyzing agents. Significant infections can also cause a change in vital signs, such as repeated febrile episodes as well as tachycardia, hypotension and tachypnea, and if not recognized and treated can lead to septic shock. In an ICU patient, these vital sign derangements may be the only reliable indication of an infection.

Laboratory Analysis

Persistent or increasing leukocytosis, often associated with an increased count of segmented neutrophils, should also raise suspicion of an infection of surgical and postoperative ICU patients. Other valuable parameters especially for monitoring the clinical course of the infectious disease process include acute phase proteins such as C-reactive protein and procalcitonin, a precursor of the hormone calcitonin [33]. Organ-specific parameters may prove helpful in potentially locating an abscess, such as altered liver function parameters in the setting of an intrahepatic abscess.

Cultures are an important tool for tailoring antibiotic regimens and assessing the course of disease. Blood cultures should be drawn in the setting of presumed sepsis and unexplained febrile episodes. Fluid draining from seromas and hematomas can be cultured, as well as aspirate from superficial and deep abscesses. The use of aspiration and analysis of peritoneal fluid in the setting of peritonitis remains controversial, especially as these cultures are often sterile in the setting of persistent secondary or tertiary peritonitis [16]. However, when possible,
the isolation of a target organism and subsequent susceptibility testing are invaluable tools for the diagnosis and treatment of surgical infections.

**Radiology**

Different imaging modalities play a vital role in the setting of a surgical site infection. Radiographs can reveal free air, pneumatosasis of the bowel wall, which indicates ischemia or necrosis, or gas in the soft tissue as potential signs of a localized infection. Ultrasound can be a helpful mobile bedside tool for evaluating the presence of an abscess. It is dependent upon the ability of the ultrasonographer and the patient’s body habitus, and can be seriously limited in deep-organ spaces, when air-filled bowel loops may obstruct the view of a potential collection.

Computed tomography (CT) can be a very useful tool for evaluating deep surgical site infections, especially as image quality can be optimized by the application of intravenous, oral, or rectal contrast. This can be limited by the fact that many hemodynamically unstable patients may not be suitable for transport to the CT suite, and use of intravenous contrast can also contribute to impaired renal function.

Magnetic resonance imaging may be a helpful modality for evaluating compartments for patients whose radiation exposure should be minimized, such as pregnant or pediatric patients. Its use to assess surgical infections in intensive care patients is nonetheless limited due to the relatively long duration of the examination, and due to limited image quality of the thoracic and abdominal cavity due to motion artifacts from peristalsis of the bowel wall, as well as respiration and movement of the diaphragm.
THERAPY

Antiinfective Treatment

The general principles of antibiotic therapy apply in the setting of surgical site infections as well. Antibiotic treatment should commence as early as possible. Initially, a broad-spectrum empiric agent should be chosen, tailored to the likely site(s) of infection, local bacterial epidemiology, and known resistance patterns. Coverage is dependent on location, type, and severity of the surgical infection [34]. Usually, initial coverage includes gram negatives, gram positives, and anaerobes. One may also consider covering Candida in a high-risk setting. As a second step, antibiotic coverage is tailored to culture and susceptibility results in order to prevent the emergence of multiresistant bacterial strains [35]. Antibiotic coverage should not be prolonged unless necessary, such as in the setting of failed source control or superinfection.

Source Control

Despite adequate antiinfectious coverage, patient’s mortality rates in the setting of surgical infection may be high without proper source control [31]. Source control is defined as “all physical measures undertaken to eliminate a source of infection, control ongoing contamination, and restore premorbid anatomy and function” [36]. In order to optimize outcomes, controlling the source of bacterial contamination and the removal of infectious foci should be performed in a timely fashion [37]. Ideally, the patient should be medically optimized before source control measures; necessary medical treatment may include fluid resuscitation, establishment of adequate intravenous access, transfusion of blood products, and optimization of coagulation. However, adequate source control should not be postponed for lengthy diagnostic or radiologic studies. Depending on the underlying extent of infection, source control measures may include drainage via either the open surgical or percutaneous technique, debridement of infected and necrotic tissue, decompression, diversion, or restoration of anatomy and organ function. Clinical judgment and experience of the intensivist and surgeon are warranted for timely intervention to ensure control of the ongoing cause of infection without causing further harm to the patient.
The ideal treatment approach to surgical infections is thus multimodal. Early adequate antibiotic coverage and source control ensure optimal control over pathogens, while the patient needs to be appropriately resuscitated and nutritionally supported.
PROGNOSIS

Prognosis of surgical infection is dependent on the extent of infection, resulting organ dysfunction, adequacy of source control and antibiotic treatment, and on basic patient factors such as age and immunologic competence. Origin of surgical infection may also influence outcomes; for example, appendiceal perforation as origin of infection has been found to be associated with better outcome when compared with other perforations within the abdomen [15]. Increased knowledge about appropriate resuscitation and improved antibiotic use have also contributed to improving overall mortality rates [38]. Surgical infections in an intensive care setting remain a challenge, but timely diagnosis and appropriate management will minimize complications and enhance rates of survival.
REFERENCES

INTRODUCTION

Necrotizing fasciitis (NF) originates from the Greek word *nekroun*, to make dead and from the Latin word *fascis* meaning bundle. NF is an aggressive disease commonly known as a condition involving flesh-eating bacteria. NF is on the broader spectrum of necrotizing soft tissue infections (NSTI) which all share common signs, symptoms, etiologies, pathophysiology, and treatments. All NSTI occur in the soft tissue compartment from the dermis down to and including the muscular layer. NF specifically spreads along the fascial planes at an aggressive rate. In addition, administration of antibiotics alone does not cure this disease making it a true surgical emergency. Mortality increases significantly if wide surgical debridement is delayed, thereby placing high importance on accurate and rapid diagnosis of this devastating disease.

NF has been identified for over two millennia; the first account is ascribed to Hippocrates. Hippocrates referred to a case of complicated erysipelas disease *ca.* 500 BCE, and the specific disease manifestations he described were similar to current descriptions of NF. In the 1700s, the chief surgeon at a hospital in France, Claude Colles, described a condition that he had seen that was consistent with NF. It was not until the American Civil War when Joseph Jones, a confederate physician whose notes are one of the mainstays of medical documentation of this war, identified an organism, specifically a bacillus, as the cause of multiple cases of gangrene. After the war, Jones published documentation of over 2,600 cases of gangrene. Weaponry and physical site (e.g., farmland) of battle were thought to have contributed to numerous accounts of gas
gangrene, which led to one of the largest contemporaneous retrospective studies on gas gangrene. In his paper, he gave the first description of what we currently call NF, with a mortality rate nearing 50%. A variant of NF is Fournier gangrene and is attributed to Jean Alfred Fournier, a French dermatologist. Fournier gangrene is NF of the perianal, perineal, or genital area, which will be discussed later. He documented five cases of tissue necrosis of the perineum in the 1880s. NF became known as Meleney gangrene after Dr. Frank L Meleney discovered an association with the disease and β-hemolytic Streptococcus in the 1920s. In the 1950s, Dr. Ben Wilson coined the term NF as a more appropriate term [6].

Throughout history, despite our advances in medicine, mortality rates remain high in NSTI: reports range in the literature from 25% to 60%. One of the contributing factors to this high mortality rate is the non-specificity of symptoms. This non-specificity can make early diagnosis difficult and delay lifesaving surgical intervention, emphasizing the importance of accurate and early diagnosis. Many approaches have been developed to predict the risk of an infection truly being NF. The most commonly utilized is the LRINF (Laboratory Risk Indicator for Necrotizing Fasciitis) score described by Wong [1–6].
Epidemiology and Risk Factors

The number of cases of adult NSTI in the United States ranges from 500 to 1,500 annually with an incidence rate 0.04/1,000 person-years [1,7,8]. Comorbidities are a major risk factor for the development of NF; one study showed that greater than 80% of patients had preexisting medical conditions. The most common risk factors include diabetes mellitus, age greater than 50, obesity, malnutrition, chronic renal disease, chronic liver disease, human immunodeficiency virus, immunosuppression, hypertension, peripheral vascular disease, cancer, pulmonary disease, and intravenous drug abuse (IVDA). Some studies even suggest use of nonsteroidal antiinflammatory drugs as a risk factor [9].

The literature has repeatedly demonstrated that delayed surgical intervention, generally considered greater than 24 hours after diagnosis, is the main risk factor for mortality. Other significant mortality factors recognized are Clostridium spp. infection, development of sepsis, chronic renal disease, cardiac or pulmonary disease, IVDA, and malignancy [1,9–11].
ETIOLOGIES

Most cases of NF are associated with a particular trauma or inciting event, allowing the pathogen to be inoculated through a break in the epidermal or mucosal surfaces into the subcutaneous tissue. NF is most commonly reported in the lower extremities, perineum, and the genitalia but can occur anywhere on the body. Documented sources of NF include skin infections (abscess), trauma, infected foot ulcers, surgical wound, perforated viscus, animal and insect bites, needle sticks (IVDA or subcutaneous insulin injection), percutaneous procedures, infected grafts, pressure ulcers (sacral decubitus ulcers), burns, or incarcerated hernias. While most cases of NF are trauma related, anywhere from 15% to 52% are idiopathic [1,2,4,6,9,10,12,13].
PATHOPHYSIOLOGY

Layers of skin from superficial to deep are epidermis, dermis, subcutaneous layer (hypodermis or superficial fascia), and deep fascia. The superficial fascial layer is termed dartos fascia in the genitalia, which is a continuance of the Colles fascia in the perineum, and the Scarpa fascia of the abdominal wall.

The disease course is similar regardless of the etiology or location. Once the pathogen has been inoculated into the subcutaneous tissue, it begins to replicate. The severity of infection is also determined by other factors including the size of the inoculum, virulence of the pathogen, blood flow to the tissue, presence of foreign bodies, as well as host response. Pathogens that are more virulent, if polymicrobial, work synergistically allowing for rapid reproduction in an anaerobic environment. Enzymes begin to necrose the hypodermis and cause vascular thrombosis of the nutrient vessels located in the hypodermis, leading to ischemia and edema (Fig. 49.1). Ischemia of the nerves causes hypoesthesia, anesthesia, and hyperesthesia (pain out of proportion to physical examination). Crepitus on physical examination and subcutaneous air seen on imaging is caused by the gas-forming anaerobic pathogens. The hypodermis is more likely to develop necrosis leading to the expected later finding of overlying epidermal and dermal changes, once the cutaneous circulation has thrombosed. This leads to erythema, edema, both serous and hemorrhagic bullae, and frank necrosis [1,2,7–9].

FIGURE 49.1 A: Patient with left lower extremity tissue necrosis, erythema, and edema consistent with necrotizing fasciitis. B: The same patient after wide
surgical debridement.
CLASSIFICATIONS

Originally two types of NF were proposed. However, due to increased research and documentation, that classification has been expanded to a third and fourth type of NF as described by Misiakos et al. [8] These classifications are based on the bacteria as well as the number of bacteria causing NF. These classifications are also important for directing treatment which will be discussed in a later section.

Type I: Polymicrobial

This is by far the most common type of NF, accounting for upward of 70% of NF. Type I is generally seen in the elderly population and those with multiple comorbidities. Most of these infections are located in the trunk or perineum. At least two pathogens are detected in the surgical specimen culture, with an average of over four species identified. In historical terms, Clostridium spp. played a large role in type I NF. In more recent years, the incidence of Clostridium has declined significantly and is rare. This is thought to be due to improved sanitation, hygiene, and sterilization techniques. Clostridium is commonly found in soil in endemic areas of the United States and the world with rates around 10%. For further discussion of Clostridium, please refer to our discussion below of type 3 NF [1–3,7–9,13].

Fournier gangrene (Fig. 49.2) is considered a subtype of type I NF because it is a polymicrobial infection. Fournier was first described as a necrotizing infection of the penis and scrotum. Today’s definition is a little broader, and now includes the genitalia of both male and females, perineal, and perianal areas. Particular considerations with this type of NF are that Scarpa fascia is continuous with Colles fascia and dartos fascia. This allows for the disease to spread easily from the groin superiorly to the anterior abdominal wall, making control of this disease more difficult [1–3,7–9,13–15].
Type II: Monomicrobial Gram Positive (β-Hemolytic Streptococcus A alone or with MSSA or MRSA)

Group-A β-hemolytic streptococcus (gram-positive catalase-negative cocci in pairs or chains), also referred to as GAS, is the hallmark of type II NF. It can either occur by itself or in conjunction with Staphylococcus aureus (gram-positive cocci catalase-positive in clusters), and both methicillin sensitive (MSSA) and methicillin resistant (MRSA). GAS (Streptococcus pyogenes) has evolved to include several mechanisms to increase its toxicity; most importantly for the discussion of pathophysiology is the M protein. The M protein allows GAS to bind and activate T-cell receptors in a much larger number than would normally be activated. This causes an extremely large inflammatory response, by releasing inflammatory cytokines including interleukin-1, interleukin-6, and tumor necrosis factor-α. The M protein also leads to decreased phagocytosis by neutrophils. In addition, GAS has exotoxins that lead to neutrophil damage, decreased phagocytosis, and breakdown of connective tissue. Panton–Valentine leukocidin gene is a virulent factor seen with some S. aureus that is currently being studied and is thought to contribute to the severity of disease as well as resistance to certain antibiotic therapies [4]. With Staphylococcus spp., infection can lead to toxic shock syndrome, both by tissue necrosis and leukocyte destruction. This type of NF is more common in the extremities in young healthy patients and is commonly caused by trauma such as surgery and IVDA. Mortality rates of types I and II are comparable [2,8,9].

Type III: Monomicrobial Infection Caused by Clostridium or Gram-Negative Bacteria

Overall, type III NF is comparatively rare. The most common pathogen of type III is Clostridium spp. (gram-positive anaerobic spore-forming bacilli), with the most commonly isolated organism being Clostridium perfringens. This pathogen is associated with obstetrical and intestinal surgery, significant trauma, and IVDA. Other strains of Clostridium that have been implicated include C. septicum in patients with certain types of cancer without a traumatic injury and C. sordellii in subcutaneous
injections of a particular type of heroin. *Clostridium* species are thought to produce two main toxins responsible for their virulence: α and θ toxins. α toxin causes damage locally by impairing neutrophil function, platelet function, and diapedesis. θ toxin damage is systemically active and is thought to cause hemolysis, decreased systemic vascular resistance through decreasing peripheral tone, and impaired phagocytosis. Gram-negative bacteria include both *Vibrio* spp. and *Aeromonas* spp. *Vibrio vulnificus* (gram-negative motile bacilli) are the most common *Vibrio* spp. seen in NF and are normally found with upper extremity trauma in patients with hepatic, renal, or adrenal failure. These bacteria are observed in warmer marine water, hence an increase in incidence during the summer months. *Aeromonas hydrophila* and *A. veronii* bv. sobria (gram-negative rod or bacilli) are also aquatic, usually fresh or brackish water, but can also be normal flora in human. Usually infection with *Aeromonas* spp. leads to gastroenteritis but it can also cause NF [1,8,9,15,16].

**Type IV: Fungal**

This type is very unusual, but is often seen in immunocompromised patients with a traumatic inoculation. Type IV NF has a very rapid course that is often attributed to the comorbidities of this patient population. Fungi seen are usually *Candida* species, more specifically *C. parapsilosis* [17], *C. albicans* [18], and *C. tropicalis* [14], as well as *Zygomycetes* [8].
SIGNS AND SYMPTOMS

Physical examination is of utmost importance for patients with NF. Attention to detail, especially with change or worsening conditions within a short time period, is extremely important. Pertinent signs and symptoms are listed below. These are not specific to NF but can be suggestive of this disease.

Symptoms

- Pain out of proportion to exam
- Nausea and vomiting
- Diarrhea
- Chills

Signs

- Skin erythema, which is common in many skin conditions and is more sensitive than specific (Fig. 49.3)
- Skin discoloration, necrosis
- Bullae or blistering
- Warm to palpation
- Crepitus (more common with Clostridium or other gas-forming bacteria)
- Wound discharge, classically dishwater in character but can vary
- Induration, edema
- Laboratory anomalies (which will be discussed later)
- Fever
- Tachycardia
- Mental status changes
As the disease progresses, patients develop systemic inflammatory response syndrome (SIRS). SIRS criteria include heart rate greater than 90, white blood cell count ≤4,000, ≥12,000, or bands ≥10%, temperature greater than 38 or less than 36°C, respiratory rate greater than 20 breaths per minute or PaCO₂ less than 32. Despite adequate treatment, a number of patients develop septic shock with multiorgan dysfunction syndrome.
DIAGNOSTICS

Once again, physical examination is most important for the diagnosis of NF. The aforementioned symptoms can be detected on examination but there are other tools to assist in making the diagnosis.

Microbiology

Drainage from the wound can be sent for gram stain and culture. The culture takes 24 to 72 hours to identify the pathogen, but if gram stain is positive for gram-positive cocci or bacilli, this will aid in making the diagnosis, especially in conjunction with other signs and symptoms exhibited by the patient.

Surgical Biopsy

This can be done at the bedside or in the operating room if clinical suspicion is high. The main objective is to evaluate the fascia. Discoloration and peeling of unhealthy fascia is pathognomonic for NF. Surgery is the only definitive method of diagnosis for NF. This is the only way to truly evaluate fascial involvement.

X-Rays

This may show air within subcutaneous tissue and musculature with edema (Fig. 49.4). Radiography tends to be more useful with *Clostridium* or gas-forming bacterium due to the subcutaneous emphysema.

![Figure 49.4](image)

A: The patient is an 80-year-old diabetic immunosuppressed male with right ankle/foot erythema, ecchymosis, bullae, discharge,
and edema. B: X-ray of the ankle shows soft tissue swelling and gas. Serous discharge was sent for gram stain, and culture demonstrated a polymicrobial infection. He was diagnosed with necrotizing fasciitis (NF) \[15\].

### Commuted Tomography (CT) Scan

CT scans can be helpful in making a diagnosis, especially with patient history and an examination. Stranding on CT is suggestive of inflammation. Air within fascial planes can also be better visualized on CT scans than X-rays.

### Magnetic Resonance Imaging

This can also be useful in making the diagnosis, and is the most sensitive imaging. However, CT scan is often more efficient. If the diagnosis is still uncertain, including both laboratory values and physical examination, a CT scan can be obtained, saving both cost and time compared to magnetic resonance imaging (MRI).

### Ultrasound

There is some evidence showing efficacy with the use of ultrasound in NF. A retrospective study evaluating the role of ultrasound in proven cases of NF revealed changes in muscle, fascia, and fat that would support evidence of an infection, but are nonspecific and are user dependent \[19\].

Despite the availability of these diagnostic modalities, it is still difficult to definitely differentiate NF from other soft tissue infections. In 2004, there was a retrospective study published in the *Journal of Critical Care Medicine* on the subject of NF. The goal was to establish criteria to help differentiate NF from other soft tissue infections with a certain degree of reliability. A scoring system was developed that was very suggestive of NF if the patient scored above 6. However, about 10% of patients with scores below 6 were also found to have NF. Components of the laboratory risk factors are listed in Table 49.1. Laboratory values such as basic metabolic panel and complete blood count are routinely obtained in patients presenting to the emergency department. The C-reactive protein level is the only additional value that is required for the calculation \[6\].

Final model constructed using factors found to be independently predictive of necrotizing fasciitis (NF) on multivariate analysis. \( \beta \) values are the regression coefficients of our model after adjusting for a shrinkage factor of .89. The maximum score is 13: a score of \( \geq 6 \) should raise the suspicion of NF and a score of \( \geq 8 \) is strongly predictive of this disease. To convert the values of glucose to mg per dL, multiply by 18.015. To convert the values of creatinine to mg per dL, multiply by 0.01131.
Delay in diagnosis and time to the operating room increase mortality in patients with NF, as well as the lack of a fast and accurate imaging modality. Scoring scales based upon signs to help clinicians diagnose NF earlier have also been developed. The currently accepted scoring system is the LRINF.
TREATMENT

Surgery

The main goal when treating NF is removal of the involved tissues. Wide surgical excision is the mainstay of therapy. Patients usually require multiple returns to the operating room to evaluate the wound and to ensure all involved tissue is excised. Wounds may be left open and allowed to heal by secondary intention. Often multiple wet to dry dressing changes are required to adequately debride the tissue. Iodine, Dakin solution, as well as other chemicals can be added to the early wet to dry dressings to help decrease the bacterial load in the wound. Patients may ultimately require skin grafts if the area of debridement is extensive (Fig. 49.5).

![Image](image_url)

**FIGURE 49.5** A: The patient who was previously discussed with Fournier gangrene after surgical debridement of the scrotum. B: The application of a split thickness skin graft to cover part of a large defect.

Antibiotics

Once diagnosis is made, antibiotics are started to help control the spread of the infection. Since the bacteria commonly found in this disease are gram-positive cocci, rods or anaerobes, broad-spectrum antibiotic coverage should be started initially. Once surgical cultures have resulted, the type of NF can be identified and antibiotic therapy can be targeted.
The recommended regimen consists of a β-lactam inhibitor +/- β-lactamase inhibitor (penicillin, piperillin/tazobactam), anaerobic coverage with clindamycin/metronidazole, and MRSA coverage with vancomycin. Other studies recommend use of meropenem plus clindamycin or ciprofloxacin, or clindamycin and metronidazole combination for broad-spectrum coverage. Clindamycin is also used frequently because it has been shown to decrease the release of Clostridium α-toxin as well as the Streptococcal M protein [9,13,20].

**Intravenous Immune Globulin (IVIG)**

The use of IVIG for NF is supported by some case reports and mainly as an adjunct in cases of GAS infections. It is not a widely accepted option for treatment and requires more research to evaluate its efficacy [9,21].

**Hyperbaric Oxygen Therapy**

The role of hyperbaric oxygen in NF appears to be as an adjunct. Some retrospective studies have shown an additional benefit in patients treated primarily with surgical debridement and antibiotics. At the current time, there is no randomized prospective trial evaluating the benefit of hyperbaric oxygen in these patients. Use of hyperbaric oxygen still remains controversial [9].

**Negative Pressure Wound Therapy**

Negative pressure wound therapy (NPWT) has become more popular for the treatment of large wounds. In cases of NF, NPWT is placed after surgical debridement has taken place. It has been shown that NPWT decreases cost of therapy in the long term and decreases time to complete wound healing [22]. More recently, there are case reports of adding a pure hypochlorous acid solution 0.01% (NeutroPhase, NovaBay Pharmaceuticals Inc, Emeryville, CA) for the treatment of NF. Hypochlorous acid inactivates S. aureus and S. pyogenes toxins [14]. Silver is another adjunct to NPWT described by Pour et al. in a case report that decreased hospital length of stay. Silver is thought to be antimicrobial by disabling growth enzymes [23].
CONCLUSIONS

NF is a true surgical emergency. The earlier diagnosis and intervention occur, the better the potential outcome for the patient. Surgery, which involves excision of all involved tissue, is the only known cure for all types of NF that have been discussed (types I-IV and Fournier). Antibiotics, IVIG, and other adjuncts can aid in the treatment. The difficulty is in early recognition and diagnosis. Retrospective studies have shown mortality to be between 25% and 60% [6,13]. Many factors are involved in predicting mortality, including time of diagnosis, time to surgery, patient’s comorbidities and operative risk, and level of illness (SIRS, severe sepsis, septic shock, etc.). NF can easily be confused with other soft tissue infections but a good physical examination, attention to details, and potential use of imaging studies is the preferred approach for making the diagnosis.
REFERENCES

Major surgical procedures are now routine. However, high-risk, noncardiac populations, including those who are at high risk due to the presence of cancer, are a subgroup that requires special consideration. This chapter highlights operations for common gastrointestinal (GI) cancer requiring perioperative intensive care. As morbidity and mortality after major oncologic surgery for cancer can be substantial, herein we focus on the complications specific to these operations, which can have significant implications on perioperative management and outcomes.

PANCREATIC RESECTION

Pancreatic cancer is currently the fourth leading cause of cancer death in the United States; incidence and mortality rates are currently increasing. While survival remains dismal with little improvement in recent decades, surgical resection currently offers the best option for long-term survival and cure. The type of resection is largely dependent upon tumor characteristics such as size, location, and vascular involvement. Common standard segmental resections for pancreatic cancer include pancreaticoduodenectomy (PD; also known as the Whipple procedure) and distal pancreatectomy (DP). Total pancreatectomy for neoplastic purposes may be considered for selected cases, particularly in the setting of main duct intraductal papillary mucinous neoplasm.

Perioperative management remains largely surgeon- and institution-
dependent. Early ambulation, pulmonary secretion clearance, and pain control (particularly with epidural analgesia) are paramount during the early postoperative period. Following PD, nasogastric decompression may be helpful. Once gastric decompression is discontinued, there is slow advancement of the diet. Attention should be paid to clinical signs of perioperative complications that warrant additional workup and management. Patients are at risk of postoperative diabetes and thromboembolic events and, therefore, generally receive close glucose monitoring and insulin supplementation and venous thromboembolism prevention. Feeding jejunostomies and parenteral nutrition are generally unnecessary unless a complication that would result in nutritional deficiency warrants their use.

Contemporary series of complications following PD report an overall complication rate of 31% to 38% and mortality rate ranging from 1% to 4% [1–7]. The most commonly reported complications include pancreatic fistula, hemorrhage related to pseudoaneurysm, delayed gastric emptying (DGE), and exocrine and endocrine insufficiency. Additional complications include, but are not limited to, wound infections, need for reoperation, other anastomotic leakage (biliary, gastric, or duodenal), cholangitis, pancreatitis, and complications of other organ systems reported with other operations (including deep venous thrombosis, pulmonary embolus, cardiopulmonary complications, cerebral complications including stroke, and urinary tract infection).

This discussion will focus on the common complications specific to pancreatic resection, including pancreatic fistula, hemorrhage related to pseudoaneurysm, DGE, and endocrine and exocrine insufficiency.

**Postoperative Pancreatic Fistula**

Postoperative pancreatic fistula (POPF; also known as pancreatic leak) remains a difficult management dilemma, which contributes significantly to postoperative morbidity and mortality. Numerous reports have been published exploring the incidence of this complications as well as means by which to prevent and treat this issue. The reported incidence of POPF is highly variable, ranging from 2% to 12% [1–6]. Many groups have proposed definitions based on surgical drain output quantity and quality, but the most commonly adopted terminology arises from the International Study Group on Pancreatic Fistula (ISGPF). This group defines POPF as “failure of healing/sealing of the pancreatic-enteric anastomosis or a parenchymal leak not directly related to the anastomosis” [7]. More specifically, the ISGPF consensus defines POPF as drain fluid output on postoperative day 3 with a fluid amylase level more than three times greater than a concurrent serum amylase value.

Within this system, POPFs are graded A through C based on the degree
of severity and impact on the patient’s clinical condition and management (Table 50.1). Grade A POPFs are generally short-lived and of little clinical significance. As the patients are clinically well with without signs of infection, these do not result in changes in management. Grade B fistulas are characterized by patients who are generally well, but may have a change in management: alteration in diet (i.e., nothing by mouth), use of parenteral nutrition, use of antibiotics if an infection is present, and/or use of octreotide. A postoperative collection, which preferably is drained via a percutaneous or endoscopic approach, may be identified on imaging and addressed. Grade C POPFs are considered the most severe and are defined by a clinically unwell patient who may be septic. These POPFs require major changes in management, including reoperation and delay in discharge, and may be associated with severe complications including death.

^aIncludes change in diet, use of parenteral nutrition, antibiotics, somatostatin analogs, minimal invasive drainage. Amended from [7].

Conservative management of POPF is the mainstay of treatment. As noted previously, clinically insignificant Grade A POPFs do not require alterations in diet or additional medications. However, for more severe
Grade B-C POPFs, bowel/pancreatic rest (i.e., nothing by mouth) and the use of parenteral nutrition (i.e., total parenteral nutrition [TPN]) may be necessary. Routine use of postoperative TPN is generally not necessary and has been associated with a higher risk of major complications [8]. When collections are present, drains (whether placed surgically or postoperatively via a percutaneous approach) allow for control of contamination. Antibiotics should be introduced for signs of infection or sepsis. Reoperation is uncommon, but should be considered in the setting of an unstable patient or in one who fails conservative management.

Extensive reports have discussed, and continue to lead to a debate about, the role of octreotide in the prevention and treatment of POPF [9–14]. Octreotide is a somatostatin analog and inhibits pancreatic secretion. Initial work reported a decrease in the postoperative complication rate, including POPF, with routine octreotide administration. However, two studies performed in the United States evaluated the role of octreotide following PD and failed to demonstrate a significant impact on postoperative complications, including POPF [11,14]. Pasireotide, a somatostatin analog with a longer half-life than octreotide and a broader binding profile, was recently reported to decrease the rate of clinically significant POPF following both PD and DP [15].

Similar to the role of octreotide, there is an extensive body of literature on proposed technical means to decrease the incidence of POPF. It is generally accepted that careful handling of the pancreas and preservation of the blood supply are critical to minimize morbidity. Variations in the technical construction of the pancreatic anastomosis have been explored. Multiple studies, including a recent multicenter randomized controlled trial, have failed to demonstrate that there are differences in the rate of fistula, irrespective of whether a pancreaticojejunostomy or pancreaticogastrostomy is performed [16–19]. Variations in reconstruction, with “binding” techniques, “invagination” techniques, and duct obliteration have been met with different levels of success [20–24]. To date, a single method of pancreatic reconstruction has not been accepted as superior to others. At least with DP, there appears to be no difference in POPF or mortality whether the pancreatic stump is hand sewn or stapled [25].

The role of surgically placed drains for the prevention of POPF remains controversial. In a single-institution, prospective, randomized trial, intraoperative drain placement was associated with no overall increase in complications, but placement was associated with a significantly greater incidence of intraabdominal abscesses/collections [26]. The authors evaluated their more recent experience and again demonstrated that operatively placed drains were associated with a longer hospital stay, increased morbidity (including fistula rates), and increased readmission
rates [27]. A multicenter, prospective randomized trial recently demonstrated that subjects who did not have routine intraoperative drainage had a higher incidence of gastroparesis, intraabdominal fluid collection and abscess, severe diarrhea, need for additional drainage, and prolonged length of stay [28]. Therefore, whether surgical placed drains should be routinely placed, particularly after PD, remains unclear.

**Hemorrhage Related to Pseudoaneurysm**

Pseudoaneurysm, particularly pseudoaneurysm of the gastroduodenal artery (GDA) following a PD, is a life-threatening surgical emergency. Patients with GDA pseudoaneurysms most commonly present with abdominal pain, massive GI hemorrhage (presenting as hematemesis, melena, or hematochezia) and hemoperitoneum. Computed tomography (CT) angiogram may confirm the diagnosis, and embolization by interventional radiology can control the hemorrhage. However, if embolization fails or the patient remains unstable, exploration and control of hemorrhage is warranted. It is critically important to have a high level of suspicion for this complication: if recognized and treated expeditiously, mortality is up to 15%. If untreated, mortality approaches 90% [29].

**Delayed Gastric Emptying**

The definition of DGE is variable. The International Study Group of Pancreatic Surgery (ISGPS) defines DGE as “the inability to return to a standard diet by the end of the first postoperative week” and includes prolonged nasogastric tube (NGT) use [30]. The pathologic mechanisms are poorly understood, though it has been proposed that duodenal resection, remnant duodenal length, disrupted innervation (i.e., the duodenal intestinal pacemaker), changes in motilin levels, and mechanical narrowing at the anastomosis may contribute to DGE. If DGE occurs, it is important to rule out additional etiologies, such as a POPF or collection, which might be contributing. The reported incidence of this common complication, particularly after PD, ranges from 7% to 16% [1–6].

It was thought that the risk of DGE would be decreased with pylorus-preserving pancreaticoduodenectomy (PPPD), compared to a standard PD in which the pylorus is resected en bloc. However, multiple trials have failed to demonstrate a difference in this complication based on the preservation or resection of the pylorus [31–33]. Several studies have, in fact, suggested a higher incidence of DGE after PPPD [30].

Gastric decompression with a NGT is an important component of management, particularly for a vomiting patient who is at risk of aspiration. Motility agents such as metoclopramide and erythromycin are
first-line agents. The latter has been shown to significantly reduce the incidence of DGE from 30% to 19% following resection [34]. If DGE is prolonged, enteral nutrition via a nasojejunostomy or gastrostomy tube, or parenteral nutrition should be considered to optimize nutritional status. If a mechanical obstruction is identified, endoscopic dilation should be considered.

**Endocrine and Exocrine Pancreatic Insufficiency**

The incidence of postpancreatectomy endocrine and exocrine insufficiency has been most commonly reported among studies focusing on the chronic pancreatitis population. The risk for this population is perhaps greater than for the non-pancreatitis (i.e., neoplastic) population as pancreatic resection entails removal of at least some of the little remaining functional parenchyma. The estimated incidence of new onset diabetes following PD ranges from 11% to 54%. The risk of exocrine insufficiency followed PD has been reported as 24% to 78% [35–41]. The reported incidence from a similar population may be as high as 50% for endocrine and exocrine insufficiency, respectively, following DP [42,43]. Postoperative endocrine insufficiency is management with oral hypoglycemic or insulin. Postoperative exocrine insufficiency may be detected by continued postoperative weight loss or steatorrhea, and may be treated with enzyme supplementation.
ESOPHAGEAL RESECTION

Esophageal and gastroesophageal junction (GEJ) cancers remain therapeutic challenges with 5-year survivals of approximately 18% [44]. Due to substantial morbidity and mortality of esophagectomy as well as the large number of patients with advanced disease in whom surgery in unlikely to be curative, there has been an increasing interest in nonsurgical options, including endomucosal resection, endoscopic ablation with techniques such as photodynamic therapy, and definitive chemoradiotherapy [45]. However, esophagectomy currently remains the best option for long-term survival and cure in early stage disease and to achieve local control (e.g., reduction in the risk of tracheal or bronchial obstruction) of locally advanced disease.

Common operative approaches include the Ivor Lewis esophagectomy, McKeown esophagectomy, Sweet procedure (left-sided thoracotomy), left thoracoabdominal approach, and the transhiatal esophagectomy. A number of factors determine the operative approach, including tumor location and stage, extent of lymphadenectomy, conduit options (e.g., stomach, colon, and small intestine), patient characteristics, and surgeon preference. There is ongoing debate about a number of issues, including the role of minimally invasive surgery, the extent of lymphadenectomy, and the location of the anastomosis (cervical versus thoracic). A more thorough analysis of these ongoing debates is beyond the scope of this chapter.

Chest physiotherapy, optimization of pain control (for instance with epidural analgesia), early ambulation incentive spirometry, careful fluid management, and early extubation, when possible, are paramount to try to minimize perioperative morbidity. Chest tubes and nasogastric decompression to prevent dilation are commonly employed, the latter to reduce distension which can lead to regurgitation and aspiration. The role of feeding jejunostomy or nasoduodenal tube placement for perioperative enteral feeding is variable among surgeons. Some advocate placement to allow for nutritional optimization, particularly if inadequate or delayed diet advancement is anticipated. While some surgeons will proceed with diet advancement based on the patient’s clinical picture, a swallow study with Gastrografin contrast is the gold standard for diagnosis of complications, such as esophageal leak, and may be pursued prior to diet advancement.

Commonly reported complications include those named elsewhere in this chapter (such as cardiopulmonary complications including arrhythmias, pneumonia, and thromboembolic events), but specific to esophagectomy, morbidity can arise from esophageal anastomotic leak,
DGE, dumping syndrome, anastomotic stricture, regurgitation and reflux, chylothorax, and hemi-vocal cord dysfunction from damage to the recurrent laryngeal nerve injury.

Esophageal Anastomotic Leak

Series from large volume centers have reported leak rates of approximately 10% [46–49], though an incidence of greater than 30% has been reported for low volume centers [50]. However, differences in operative techniques, such as stapled or hand-sewn anastomosis, have not necessarily shown to reduce this complication rate [51].

Within the first 48 hours of surgery, if a patient develops shock, one must consider hemorrhage or a fulminant leak due to anastomotic necrosis or gangrene. A chest X-ray (CXR) or CT, when patient stability allows, may help differentiate between etiologies and with the latter, localize blood, when present. Exploration is generally indicated for unstable patients. Should the anastomosis be the culprit, anastomotic resection with preservation of maximal esophageal length, cervical esophagostomy, and wide drainage is performed.

More commonly, esophageal leaks may be incidentally detected on radiologic studies (such as the planned Gastrografin swallow) or may be clinically apparent about a week after surgery. One should suspect an esophageal leak in a patient with fevers, tachycardia, tachypnea, shortness of breath, and shoulder pain. In the setting of a cervical anastomosis, neck pain or cellulitis may be present. The diagnosis may be confirmed on Gastrografin swallow or CT of the chest and/or neck with oral contrast, which may show a pleural effusion or pooling of oral contrast. If a chest tube is in place, drainage may be foul-smelling or turbid.

If the patient is hemodynamically stable, the patient may be managed conservatively with drainage, nutrition optimization, and antibiotics based on culture data. Proton pump inhibitors that reduce gastric acid secretion may be helpful. However, if these maneuvers fail or if the patient is unstable, re-exploration with drainage should be considered. Primary repair may not be possible in this setting. For cervical anastomotic leaks in a stable patient, the leak may be drained by opening the wound. When a leak is believed to be healed, a repeat Gastrografin swallow study can confirm healing prior to diet initiation. Upon diet advancement, instillation of methylene blue dye in clear liquids will also allow for determination of an active leak.

Delayed Gastric Emptying

DGE following esophagectomy is a common complication and can occur due a number of proposed mechanisms, including the presence of
vagotomy, reduced volume, inadequate emptying after gastric conduit creation, spiraling of the gastric tube, narrowing at the diaphragmatic hiatus, and inadequate pyloromyotomy or pyloroplasty. The Pittsburgh group demonstrated that the risk of DGE is about 2%, and it is believed that using a pyloroplasty, rather than pyloromyotomy, may contribute to a lower rate \[^{47}\]. Similar to DGE associated with pancreatic resection, medications such as metoclopramide and erythromycin may be used to alleviate symptoms. Endoscopic pyloric balloon dilation may be useful for cases in which an intact pylorus is contributing to the symptoms.

**Chylothorax**

Chylothorax will occur in approximately 3% of cases \[^{47}\] and arises from leakage of chyle from the thoracic duct or its branches with subsequent accumulation in the pleural space. While uncommon, it can lead to significant morbidity and mortality, related to sepsis, acute respiratory distress syndrome, pneumonia, and need for reintubation.

Signs of this complication include drainage of an excessive amount of straw or cream-colored fluid, a contralateral pleural effusion, or milky fluid when enteral nutrition is given. The fluid has a characteristic lymphocytic predominance and high triglyceride levels (>110 mg per dL). If the triglyceride level is <110 mg per dL, the presence of chylomicrons can confirm the diagnosis. Lymphangiography may be used to diagnose and assess the degree of thoracic duct leak.

First-line management is conservative, including control of the initiating cause (if not related to the operation), adequate pleural drainage, and lung re-expansion, such as with a chest tube, and nutrition modification. Medications such as octreotide and somatostatin are rarely used. A reduced fat diet (<10 g per day) with avoidance of long-chain triglycerides and substitution with medium-chain triglycerides, and consideration of parenteral nutrition is recommended. If nonoperative measures fail, one may consider chemical pleurodesis or operative ligation of the thoracic duct (thorascopically, via thoracotomy, or via laparotomy). There are increasing reports about the role of percutaneous embolization via the cisterna chyli as an effective treatment, with up to a 70% success rates at some centers \[^{52}\]. When these surgical maneuvers fail, pleuroperitoneal or pleurovenous shunts may prove beneficial.

---

**Anastomotic Stricture**

Postoperative dysphagia may be functional or mechanical, the latter due
to anastomotic stricture. Dysphagia after esophagectomy is one of the more commonly reported complications, in part because of its subjective nature. The diagnosis may be suspected from clinical history and from upper endoscopy or upper GI radiography. Early strictures are generally benign, due to etiologies, such as scar tissue. If symptoms require, esophageal dilation can ameliorate symptoms. One should suspect recurrent cancer in the setting of late strictures. In these situations, upper endoscopy and staging studies may help elucidate the cause.

**Dumping Syndrome**

Following both esophagectomy and gastrectomy, dumping syndrome can be a common complication, associated with a spectrum of disease severity. Causes are similar to that of DGE. Symptoms result when hypertonic enteral feeds result in the translocation of fluid into the intestine, resulting in hypovolemic symptoms and/or GI symptoms such as diarrhea and bloating.

First-line management involves dietary modification, including a postgastrectomy diet of six small meals per day, limitation of foods high in monosaccharides, substitution of monosaccharides with polysaccharides, avoidance of dairy products, and limitation of excessive fluid intake after meals.

**Recurrent Laryngeal Nerve Injury**

Recurrent laryngeal nerve injury is an uncommon complication following cervical anastomoses, with an incidence reported to be as low as approximately 3% in high volume centers [47]. Due to the risk of pulmonary complications, it is a complication that should be diagnosed and treated early. The diagnosis may be made with bedside laryngoscopy, which allows for vocal cord visualization. Treatment initially is supportive and includes assessment by speech pathology. However, if necessary, vocal cord injection may improve glottic closure. If this fails, surgical intervention can accomplish vocal cord medialization.
GASTRIC RESECTION

Gastric cancer is the second leading cause of cancer deaths worldwide. In the United States, surgical resection with a total or subtotal gastrectomy with chemotherapy or chemoradiotherapy provides the best option for long-term survival and cure [53]. Postoperative morbidity risk is vaguely described. Particularly after total gastrectomy (TG), which is used for high-risk patients (i.e., those with a CDH1 mutation), GEJ tumor, tumors of the proximal and middle stomach, and diffuse tumors, morbidity can approach 40% and mortality up to approximately 11% [53]. Complications include wound issues, anemia, cardiopulmonary complications, thromboembolic events, and anastomotic stricture. However, complications specific to gastrectomy, and particularly TG, including duodenal stump leak (DSL) and anastomotic leak, will be discussed here.

Similar to other cancers, the extent of resection is based upon the site and extent of the primary tumor. While TG may be used in specific cases noted above, a more limited resection, involving a proximal or subtotal resection, may be employed if margins are adequate and oncologic outcome is not compromised. The extent of lymphadenectomy and its impact on oncologic outcome remains debatable. However, an extended, D2 lymph node dissection, with a minimum of 15 nodes harvested, is the standard at this time.

Perioperatively, early ambulation, pulmonary secretion clearance measures, judicious fluid management, and pain control are paramount. Postoperative control with epidural analgesia should be considered. There is variability regarding the use of NGTs based on the extent of resection, though NGTs are generally employed after TG. Similar to esophagectomy, Gastrografin swallow study remains the gold standard to rule out postoperative anastomotic leaks. Some clinicians elect to forgo such a study for asymptomatic patients, as a leak in an asymptomatic patient is unlikely to be clinically significant. Diet is generally advanced to a postgastrectomy diet (see “Dumping Syndrome” section). The use of a surgically placed feeding jejunostomy tube is variable. When used, enteral feeding may be initiated and advanced slowly until the patient’s oral intake is sufficient.

Esophagojejunal Anastomotic Leak

A substantial contribution of morbidity and mortality after TG arises from leakage from the esophagojejunal (EJ) anastomosis following TG with Roux-en-Y EJ. Reported EJ leak rates range from 0.5% to 13%. EJ
leaks can be associated with significant morality, reported as high as 18%. Many groups have evaluated variations of surgical techniques to reduce the risk of EJ leakage (i.e., open versus laparoscopic, circular versus linear staplers), and all techniques appear largely comparable [54].

If an EJ leak is suspected in a stable patient, for instance when an otherwise clinically well patient develops tachycardia, tachypnea, abdominal pain, or an increasing left effusion, a Gastrografin upper GI swallow study may confirm the leak as an area of extravasation. A CT scan of the chest and abdomen with Gastrografin oral contrast may confirm pooling or leakage of contrast from the anastomotic site. If a small, contained leak is identified, patients may be managed conservatively with nothing by mouth and parenteral nutrition. Antibiotics should be considered with a suspected infection. Once healing is confirmed, often with a Gastrografin swallow study, oral diet may be resumed.

Reoperation may be necessary for an unstable patient, or for a patient with peritonitis or failure to resolve nonoperatively. In some circumstances, wide drainage with enteral feeding access (jejunostomy tube versus nasojejunal tube) may be sufficient. However, if a complete EJ dehiscence is identified, it might be necessary to take down the EJ and create a cervical esophagostomy with a feeding jejunostomy tube.

There are an increasing number of recent reports discussing the role of esophageal stents, particularly as an alternative to reoperation in high-risk patients. Theoretical benefits are that placement of a stent might allow for early enteral nutrition and be associated with a lower morbidity than reoperation. In comparison with non-stent endoscopic therapies (such as fibrin glue and endoscopically placed clips), esophageal stents had a greater sealing rate. Complications of stenting can include stent migration and non-sealing [55].

**Duodenal Stump Leak**

DSL is an uncommon complication (up to 3%) but can be severe and result in substantial morbidity and mortality [56,57]. Proposed risk factors include increasing age, inadequate closure of the stump, devascularization, duodenal distension (i.e., afferent loop syndrome), and local irritation from inflammation (i.e., pancreatitis), or hematoma [56,58]. Recently, reports on DSL are becoming less common, particularly with fewer resections (and therefore complications) in the setting of peptic ulcer disease. First-line therapy is conservative management. As with other complications, nutritional optimization may improve healing. If an intraabdominal abscess is identified, percutaneous drainage should be considered. If feasible, percutaneous biliary decompression may reduce the fistula output.
If unsuccessful, if the patient is unstable (such as with hemorrhage or sepsis), or if peritonitis is present, exploration, washout, and drainage is indicated [56]. Tube duodenostomy or Roux-en-Y duodenojejunostomy (particularly if a disrupted stump that cannot be closed or if a tube duodenostomy cannot be placed) may be considered based on the degree of contamination and inflammation. The former option converts a DSL to a controlled fistula and should be considered if primary closure of the duodenal stump is tenuous or not feasible. In the setting of hostile abdomen, these complex operations, such as PD, are generally avoided.
COLORECTAL RESECTION

Colorectal cancer is the third leading cause of cancer death in the United States. The risk of death has been declining in recent years, in part due to screening colonoscopy and precancerous polyp removal. The overall lifetime risk of developing colorectal cancer is 5%.

Surgical resection, chemotherapy (including targeted treatments), and radiotherapy may be used in various combinations based on the tumor location (colon versus rectum), tumor stage, and patient characteristics. Colectomy, which may be partial (segmental) or total, can be performed for colonic cancers. Increasingly, minimally invasive techniques, such as laparoscopic, laparoscopic-assisted, or robotic approaches, may be used in addition to the traditional open operations. Low anterior resection and abdominoperineal resections may be used for more distal colon and rectal cancers not amenable to local resection. The focus of this chapter will be related to complications of these latter two operations.

Typically, due to the high bacterial load in the colon, preoperative bowel preparation is indicated. There is controversy on what constitutes a bowel preparation and specifically, the role of a mechanical bowel preparation, preoperative oral antibiotics, and perioperative parenteral antibiotics. However, most would agree that a bowel preparation, of some type, is indicated [59].

The complications of surgery for colorectal cancer are similar to those noted above. However, some complications, such as anastomotic leaks as well as sexual and urinary dysfunction, deserve specific note.

Anastomotic Leak

Anastomotic leakage will occur in up to 20% of cases, usually within the first 7 days after surgery. Signs and symptoms may include fevers, tachycardia, increasing abdominal pain including peritonitis, or the presence of a fistula. If suspected, the diagnosis may be confirmed on an upright CXR, which can show free air. A CT scan of the abdomen and pelvis might demonstrate a postoperative fluid collection with air bubbles, possibly with accumulation of passed oral contrast. While awaiting confirmation, patients should be made nothing by mouth, and broad-spectrum parenteral antibiotics may be initiated.

Anastomotic leaks may be managed conservatively with bowel rest, intravenous antibiotics, and percutaneous drainage for a clinically stable patient without peritonitis. However, for a patient who is unstable, who has peritonitis, or who fails nonoperative management, exploration, abdominal washout, wide drainage, and diverting ileostomy or colostomy
should be considered.

**Genitourinary Dysfunction**

Inadvertent injury to the sacral splanchnic and hypogastric nerves during rectal mobilization may lead to urinary and sexual dysfunction following rectal surgery. Radiation may further compound sexual dysfunction. More than 50% of patients will have a reduced sexual function and about one-third will have alterations in urinary function. In men, sexual dysfunction may manifest as impotence and difficulties with ejaculation; women may experience dyspareunia and vaginal dryness. These known complications carry with them a significant reduction in psychosocial well-being and quality of life [60]. It remains unclear if laparoscopic resection offers any benefits compared to open surgery regarding these complications.

If urinary dysfunction is a concern, particularly if there is involvement of the membranous urethra, Foley catheterization should be continued for an extended duration in the perioperative period. Patients may be discharged with a Foley catheter in place, to be discontinued later in the postoperative period. For sexual dysfunction in men, once recovered, a penile prosthetic device can be considered.
REFERENCES

6. Martin RF, Rossi RL, Leslie KA: Long-term results of pylorus-

While definitions of the “acute abdomen” differ, most clinicians will use this term to describe the sudden onset of severe abdominal pain of unclear etiology that frequently indicates the presence of a surgical pathology. Under ideal circumstances, a detailed history (including comorbid illness and prior surgeries), a thorough physical examination, ordering appropriate laboratories, and targeted imaging would reveal the source of the symptoms. The challenge for the intensive care physician begins with the many potential obstacles to early diagnosis, including altered patient sensorium, limited ability to communicate due to mechanical ventilation, concurrent antibiotic therapy, and the masking of reliable physical examination signs.

Abdominal catastrophes for intensive care unit (ICU) patients occur frequently among patients admitted for nonsurgical problems, and other systemic comorbidities, such as pulmonary, cardiovascular, renal, or multisystem disorders [1]. An acute abdomen of an already critically ill patient portends high mortality, especially for patients meeting criteria of severe sepsis, often with derangements of more than one organ system associated with widespread cellular dysfunction. Successful management of the acute abdomen of a critically ill adult has traditionally relied upon clinician-dependent factors such as sharp clinical acumen, early collaborative efforts, and diagnostic expediency, as much as evidence-based algorithms. Despite improvements in data collection and the integration of dedicated specialists into patient care plans, high-quality evidence and specific clinical guidelines are still inadequate [2].
In a 5-year retrospective cohort study of 6,000 medical ICU admissions, 77 patients were identified with acute abdominal syndromes requiring surgical intervention, suggesting it may be a rare occurrence among critically ill patients [3]. Mortality of this group peaked at 63%, more than doubling APACHE III-predicted mortality (31%). In contrast, a 2-month prospective, observation cohort of 484 ICU patients from mainland China with severe sepsis demonstrated abdominal sources (18%) to be the second most common source of infection (behind lung) and carried a high mortality (~25%) [4]. Mesenteric ischemia was associated with both early and late mortality in a single-center, retrospective study of 543 patients over 6 years, causing 6.4% of early ICU deaths and 16.6% of late ICU deaths [5]. An observational study of 3,665 patients in 10 Chinese surgical ICUs found the abdomen to be the most common source of severe sepsis among critically ill patients (72.3%). Diagnoses included severe acute pancreatitis, intestinal or gastric perforation, bowel obstruction, and biliary infection, all of which were associated with high hospital mortality (33.2% to 65.4%) [6]. The 75-country EPIC II (Extended Prevalence of Infection in the ICU) study established that 19.6% of more than 7,000 patients were found to have an abdominal source of infection using International Sepsis Forum criteria, and also showed a higher mortality rate for abdominal infections than for infections of other systems (29.4% vs. 24.4%) [7].
HISTORY

When clinical parameters permit (e.g., hemodynamic stability), a focused history should be obtained from the patient. Beyond typical historical elements (onset, quality, severity, location, radiation, exacerbating and alleviating symptoms), additional information about constitutional symptoms, gastrointestinal, and gynecologic symptoms should be obtained. Special attention should be paid to prior medical and surgery history, medications, and social history. Overall, the sensitivity and specificity of a history for the diagnosis of abdominal pain is poor. However, the information obtained from the patient may be used to identify risk factors for particular intraabdominal processes (see Table 51.1).

PHYSICAL

The traditional abdominal examination begins with inspection, which may reveal prior surgical scars, ecchymosis, areas of discoloration, and visible hernias. Long regarded an essential part of the abdominal examination, auscultation is neither specific nor sensitive [8]. Percussion may elicit tympany, suggesting ileus or obstruction. Tenderness is elicited through palpation, with rebound and guarding indicating peritonitis. Frequently, multiple signs occur simultaneously; in one study, 95% of patients with abdominal complications in a medical ICU had findings of abdominal pain, while 73% had abdominal distention and 38% had documented peritoneal signs [3]. Patients with focal pain or obstructive symptoms should be carefully examined for evidence of inguinal or incisional hernias. Rectal and pelvic examination should be performed as indicated by the symptoms and findings. Comorbid conditions such as diabetes and chronic immunosuppression may blunt examination findings associated with intraabdominal pathologies.
IMAGING

Physical examination findings may fail to provide clinical clues regarding abdominal pathologies of the critically ill patient. Diagnostic imaging provides critical clinical data during the evaluation, particularly when physical examination findings are unreliable secondary to sedation, obtundation, delirium, or immunosuppression.

Plain Radiographs

Abdominal radiographs are rapidly and widely available, inexpensive studies that are frequently obtained for patients with abdominal pain. However, the utility of abdominal radiography is highest when applied for specific indications. The American College of Radiology (ACR) recommends that abdominal radiography be used to evaluate for the following conditions in adults: pneumoperitoneum, bowel obstruction or ileus, intraabdominal foreign bodies, urinary tract calculi, and medical device placement. The ACR identifies no absolute contraindications to abdominal X-rays, with pregnancy being the only relative contraindication [9]. After an intraabdominal exploration or procedure, free air should not persist for more than 48 to 72 hours. Contrast-enhanced X-rays can be used to confirm the placement of gastrostomy and jejunostomy tubes, or to evaluate bowel motility.

Abdominal Pelvic Computed Tomography

Computed tomography (CT) is the preferred imaging modality for the diagnosis of intraabdominal catastrophes. Moreover, CT plays an essential role in limiting the number of unnecessary exploratory laparotomies performed among critically ill patients; unnecessary laparotomy is associated with morbidity for 22% of these patients [10]. Intraabdominal processes like free air, pancreatitis, diverticulitis, infections (e.g., abscesses), inflammation (e.g., colitis), acute mesenteric ischemia, and bowel obstructions are all readily identified by abdominal pelvic CT [11]. Improvements in CT technology have obviated the need for oral contrast for most patients; oral contrast should be considered for patients with a history of gastric bypass, evaluation of anastomotic leaks, and in patients with inflammatory bowel disease. When not contraindicated by allergy or renal insufficiency, intravenous contrast should be administered to optimally evaluate vascular structures (such as the superior mesenteric artery [SMA]) and abscesses. While CT does frequently identify signs of cholecystitis, ultrasound remains superior for
biliary tract (specifically common bile duct) imaging. Hemodynamic instability may preclude transport of patients to CT scan, while patients with morbid obesity may be unable to undergo a CT study due to mechanical limits.

**Ultrasound**

Ultrasound offers distinct advantages for evaluating abdominal pathologies of the critically ill care. Bedside ultrasonography is immediately available at most centers. Bedside ultrasound can be used to assess a variety of acute findings, including free fluid, pneumothorax, pericardial effusions, gallbladder disease, aortic aneurysm, intrauterine pregnancy, hydronephrosis, bladder volume, and inferior vena cava diameter (as a marker of volume resuscitation). Ultrasonography remains the test of choice for biliary tract pathologies. There are several settings in which technical limitations to ultrasound arise, including morbid obesity and the presence of bowel gas.
SPECIFIC CAUSES OF ABDOMINAL PAIN

The differential diagnosis for abdominal pain is extensive. Acute mesenteric ischemia and acalculous cholecystitis are discussed in detail here, as these are common reasons for surgical consultation for critically ill adults. Abdominal compartment syndrome, surgical infections, and necrotizing fasciitis (Fournier’s gangrene) are separately covered within this section.

Acute Mesenteric Ischemia

Acute mesenteric ischemia can be a difficult diagnosis to make, and clinicians must maintain a high degree of suspicion particularly for elderly patients with severe abdominal pain. There are several etiologies for mesenteric ischemia, including SMA embolism, SMA thrombus, superior mesenteric vein (SMV) thrombosis, and nonocclusive mesenteric ischemia (frequently associated with low-flow states). The risk factors are different for each process. Atrial fibrillation, valvular heart disease, congestive heart failure (CHF), myocardial infarction (MI), and recent vascular surgery increase the risk of SMA embolism. In these cases, the embolus is nearly always generated in the heart, then lodges in the SMA due to its angle of takeoff from the aorta [12]. Cases of SMA thrombosis are frequently associated with smoking, peripheral vascular disease, and coronary artery disease. Risk factors for SMV thrombosis include recent abdominal surgery, hypercoagulable states, oral contraceptive use, and prior history of venous thromboembolism. Nonocclusive mesenteric ischemia risk factors include low-flow states (e.g., hypotension), CHF, end-stage renal disease, and digoxin or vasopressor use [13].

Regardless of the etiology, the diagnosis and treatment of acute mesenteric ischemia are challenging. With bacterial translocation occurring 6 hours after disruption of ischemic mucosal barrier, correcting the subsequent physiologic insults is challenging, because the diagnosis takes an average of 8 hours and treatment can take another 2.5 hours [14]. Even with prompt initiation of anticoagulation for thromboembolic events with intravenous heparin (5,000 International Units bolus followed by 20,000 International Units over 24 hours), morbidity and mortality are substantial. Among patients for whom the diagnosis is delayed by 24 hours, mortality nearly doubles from 36% to 69% [13].

Cholecystitis
Acalculous cholecystitis is more frequent among the critically ill than typical stone-based disease. Acute acalculous cholecystitis reflects ischemic or inflammatory changes to the gallbladder secondary to obstruction of the cystic duct, bile stasis, or distention [15]. Risk factors include older age, male gender, diabetes mellitus, hemodialysis, CHF, cardiac arrest, or cardiopulmonary resuscitation [1]. Acute acalculous cholecystitis is frequently diagnosed among patients with an admission diagnosis of sepsis [16]. Acute acalculous cholecystitis should be considered for any ICU patient with right upper quadrant pain, fevers, and worsening leukocytosis. The most common modality for the evaluation of acalculous cholecystitis is ultrasound; however, the absence of stones can decrease the sensitivity of this test [17]. Once the diagnosis is made, treatment alternatives can be considered. Definitive therapy with open or laparoscopic cholecystectomy is associated with increased perioperative mortality among critically ill patients, leading to alternatives (percutaneous cholecystostomy tube placement) [1]. A retrospective observational study of 56 patients treated for acalculous cholecystitis with percutaneous cholecystostomy demonstrated an efficacy of over 80%, with low rates of associated complications, mortality, or need for subsequent cholecystectomy [18]. Often representing a further progression of multisystem organ failure, acute acalculous cholecystitis requires prompt intervention with low-risk surgical interventions available that can accommodate patients unfit for anesthesia or transport [19].

Extraabdominal Causes of Abdominal Pain

Several extraabdominal medical emergencies can present with abdominal pain, including MI, pneumonia, and diabetic ketoacidosis. Clinicians must remain vigilant for extraabdominal sources of pain, particularly when abdominal imaging is unremarkable or equivocal.
Abdominal emergencies impact the elderly with particular resonance. Impaired or dwindling physiologic reserves exacerbate failing organ systems and potentiate comorbidities [20]. Multidisciplinary approaches involving palliative care teams, geriatricians, primary care physicians, as well as the surgeon and intensivist, enable the identification of cases where a comfort-oriented care plan is appropriate.
MANAGEMENT

Given the possible uncertainty amid a wide spectrum of differential diagnoses for abdominal sources of sepsis of the critically ill patient, early administration of broad-spectrum antibiotics, volume resuscitation, and rapid source control must occur immediately to prevent mortality related to delay of treatments. The Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock, 2012, summarizes evidence-supported early interventions for the septic patient by international consensus and are appropriate for the critically ill patient with abdominal sepsis. Recommendations include quantitative resuscitation with appropriate reevaluation of end points, acquisition of blood cultures prior to initiation of broad-spectrum antibiotics, prompt acquisition of ancillary imaging, and source control by appropriate modality (with consideration of risks and benefits) within 12 hours.

Hemodynamic lability in such circumstances may prevent patient transport, increasing the burden on the clinician to work with physical examination, and available laboratory, and ancillary bedside diagnostics. High clinical suspicion of intraabdominal sepsis in these circumstances warrants exploratory laparotomy and its associated high mortality and morbidity [11]. When associated with hypothermia, acidosis, and coagulopathy, the mortality risk becomes nearly prohibitive. Wide surgical source control of devitalized tissues, perforated viscus, or anastomotic failures remain a priority to reduce both bacterial load and source [21]. Bowel edema secondary to resuscitation, ongoing or unresolved contamination from perforated or compromises viscous, and clear anticipation of abdominal compartment syndrome may warrant leaving the abdomen open with placement of a negative pressure wound therapy device [22]. Open abdomens in the non-trauma patient have become more widely described in recent years with concerns noted for high mortality and enterocutaneous fistula formation, but with the caveat that many of these scenarios are predisposed to both outcomes as expected sequelae of inflamed, swollen bowel and severe sepsis [23,24]. There exists substantial heterogeneity regarding the indications for the open abdomen among critically ill patients, whether deliberate or unavoidable. While initial maneuvers performed during source control (damage control) surgery require debridement of devitalized tissues, removal of infected foreign bodies, irrigation and drainage of contaminated surfaces, and abdominal decompression, the subsequent restoration of anatomic function is less of an immediate priority [25]. An emerging literature has embraced delayed reconstruction of bowel continuity, with some indication that resuscitation and optimization of
anastomosis creation may lead to improved survival and fewer complications [26].
CONCLUSIONS

Intraabdominal source control, prompt administration of antibiotics, and the application of due diligence to fluid resuscitation and correction of physiologic derangements represent the cornerstones of an ICU approach to the acute abdomen. Impediments to the pragmatic approach and treatment of the acute abdomen include patient complexity, poor clinical correlates, and delays in diagnosis secondary to confounding from coexisting ailments. A multidisciplinary approach designed to maximize utilization of physical examination findings, laboratory results, imaging modalities, and collaborative clinical judgment results in the best opportunity for early intervention and improved outcomes.
REFERENCES

INTRODUCTION

Since intraabdominal hypertension (IAH) and abdominal compartment syndrome (ACS) were first recognized, the incidence and importance has resulted in an increasing body of research and the formation of the World Society of Abdominal Compartment Syndrome. Normal abdominal pressure is typically less than 7 mm Hg. Once pressures are greater than 12 mm Hg, the patient is considered to have IAH. As pressures increase further, organ failure can develop. Pressures greater than 20 mm Hg with new onset organ failure is considered ACS and pressures greater than 25 mm Hg are considered significant enough to consider intervening [1].

ACS can be termed primary or secondary. Primary ACS occurs from an intraabdominal process, for example pancreatitis, liver failure, or abdominal trauma. Secondary ACS is the result of illness not directly related to the abdomen or pelvis. This secondary form is caused by severe systemic illness and the resultant capillary leak and typically is related to large volume resuscitation [2].
INCIDENCE

Many factors determine intraabdominal pressures. These factors include patient-related issues such as body mass index (BMI), severity of illness such as acute lung injury requiring increased positive end expiratory pressure (PEEP) as well as the technique by which the pressure was measured. The technique will be discussed in detail below. Increased BMI correlates with increased intraabdominal pressure in multiple studies [3]. In particular, a patient population with BMI $52 \pm 1$ kg per m$^2$ had measured intraabdominal pressures of $13.2 \pm 0.5$ mm Hg as compared with patients with a BMI $24 \pm 2$ kg per m$^2$ whose measured pressures were $5.1 \pm 1.2$ mm Hg [4]. PEEP has a variable effect on intraabdominal pressure. The effects of PEEP may be greater with higher intraabdominal pressures [3].

Setting an upper limit of 15 mm Hg, the incidence of IAH exceeding this cutoff was 28% for published cohorts [5,6]. If a lower threshold of 12 mm Hg was used, nearly 50% of critically ill patients had IAH [5,7]. It is important to note that intraabdominal pressures vary during the day when serially measured and one elevated pressure may or may not be significant. How studies define IAH also varies with some studies using the maximum daily measured intravesicular pressure; other studies calculate a mean daily pressure. Using the maximum daily pressure versus the mean pressure more than doubled the incidence of IAH [5]. The World Society of Abdominal Compartment Syndrome recommends pressures greater than 12 mm Hg on more than one occasion to diagnose IAH [1].

The risk factors for development of IAH/ACS vary among studies. Fluid resuscitation impacts the development of elevated intraabdominal pressures, with positive fluid balances in the first days of intensive care unit (ICU) admission being significantly different both statistically and clinically between patients with elevated intravesicular pressures and those patients with normal measured pressures [5,7]. The administered volume associated with IAH/ACS varies widely between studies from 3.5 L to greater than 15 L [5,8]. Other factors associated with elevated intraabdominal pressure include mechanical ventilation, acute respiratory distress syndrome (ARDS) [7], abdominal surgery, ileus, and liver failure [6]. Systemic diseases such as severe trauma, major burn injury. as well as sepsis and multiorgan failure (as determined by the Sepsis-related Organ Failure Assessment score [SOFA]) also place patients at risk of IAH/ACS [1].

Overall, 20% to 40% of surgical and medical ICU patients develop IAH. Patients may arrive to the ICU already with IAH or it can develop during
their ICU stay. ACS occurs in up to 10% of these patients. Numerous risk factors are described and many case reports have been published. Many of these patient and disease factors are nonspecific making patient selection for intraabdominal pressure monitoring difficult. No clear recommendations have been published. Of the highest risk populations for IAH, severe trauma, major burn, severe pancreatitis, and liver failure patients should be considered for monitoring [9].
MEASUREMENT OF INTRAABDOMINAL PRESSURE

Many techniques have been developed to monitor intraabdominal pressure. Clinical examination has been assessed to determine its ability to detect IAH/ACS. A prospective study of 128 consecutive surgical patients admitted to the ICU compared the clinician’s examination (scored as normal, moderately tense, markedly tense abdominal examination) with intravesicular pressure which was classified unremarkable if <18 mm Hg, elevated if between 18 and 25 mm Hg, and markedly elevated if >25 mm Hg. In this population of patients with 20% having elevated intravesicular pressures, and 1% having markedly elevated pressures, the clinical examiner impression had a sensitivity of 61%, specificity of 81%, and positive predictive value of only 45% [10]. Other series confirm the finding that physical examination poorly predicts IAH/ACS [11].

Quantitative techniques have been developed and include gastric, bladder, rectal, femoral vein, inferior vena cava (IVC), and direct intraperitoneal pressure monitoring [12]. Intravascular monitoring via the femoral vein or the IVC has been reported in animal models [13]. However, the invasiveness of the intravascular approach as well as the infectious and thrombotic risks make placement of these catheters impractical. Intraperitoneal pressure monitors have been compared with intravesicular pressure monitors in 40 postsurgical patients. The peritoneal catheters used were 14 French polyvinylchloride. Five patients had postoperative IAH and only one had ACS, which required surgical intervention. The correlation between the intraperitoneal catheter with the intravesicular monitor was excellent with $r = 0.96$ and most measurements had a less than 1 mm Hg difference between the methods [14].

Intravesicular pressure monitoring as a surrogate for intraabdominal pressure is now the standard. The technique involves instilling saline into a urinary catheter; the catheter is clamped between the culture aspiration port and the urometer. After waiting for 30 to 60 seconds, the culture aspiration port is connected to a pressure monitor. There have been many concerns over the validity of this technique and it has been widely studied. In particular, the proper volume to infuse has been examined and varied from 10 mL to as much as 250 mL; one study examined the effects of 10, 50, and 100 mL instillation volumes on the measured bladder pressure. The higher instillation instillation volumes of 50 mL and 100 mL increased the measured bladder pressures by 20% and 40%
as compared to 10 mL instillation[15]. The current recommendation is the instillation of 25 mL [1].

The correct zero point has been investigated as has been the effects of different patient positions. Patient positions with the head of bed between 0 degrees (supine) and 45 degrees elevated have been shown to increase the intraabdominal pressure with increased elevation [16,17]. The most common zero point is set at the midaxillary line and iliac crest. Due to feasibility and expense, the current guidelines recommend bladder pressure assessment in a supine patient at end expiration with the zero point set at the midaxillary line [1].
The classic compartment syndrome occurs in the cranium. The cranium is a rigid enclosed space whose bounds are the cranial bones; the intracranial volume is fixed. Within the cranium lies cerebral spinal fluid, blood within the arterial and venous systems, and brain parenchyma. If any of these components increase in volume, for example the amount of intracranial blood from a subdural hematoma, then intracranial pressure increases.

The abdominal compartment has a different structure. The volume is not fixed and can expand. This difference plays an important role in treatment options. Inferiorly and posteriorly the pelvis and the spine create a rigid barrier; however, the anterior and superior bounds are not rigid. The diaphragmatic muscles contract and relax with inspiration and expiration. The anterior abdominal wall musculature which lies between the anterior axillary lines is composed of the paired rectii muscles medially and the external obliques, internal obliques, and the transversus abdominus; these muscles also can contract or relax changing the intraabdominal volume [12].

Within the abdomen there are the solid organs and the arterial–venous systems; there is also the intraperitoneal space or third space where ascites can develop. Within the lumen of the gastrointestinal tract, air and succuss can take up a significant volume, for example from an ileus or Ogilvie syndrome. An increase in the volume of any of these components can increase the intraabdominal pressure.
ABDOMINAL COMPARTMENT SYNDROME

Increased intraabdominal pressure can have systemic effects for patients. Once new organ failure results from IAH, the patient is considered to have ACS. The pressure at which IAH causes ACS varies from patient to patient. Pressures below 20 mm Hg are unlikely to cause organ failure; organ failure is much more likely to occur once pressures exceed 25 mm Hg [2]. We will individually examine each organ system that may be affected.

Respiratory Failure

Pulmonary failure from ACS can result in hypoxia and hypercarbia. As intraabdominal volume and pressure increase, the diaphragm is elevated into the thorax. This upward pressure leads to compression and atelectasis of the lungs. Due to the ventilation and perfusion mismatch, hypoxia occurs.

Lung volumes can decrease, and among intubated patients, plateau pressures and peak inspiratory pressures can increase. In a swine animal mode of IAH, 50% of the IAH was transmitted to the plateau pressure under conditions of PEEP of 1 or 10 cm H₂O [18]. When a pressure control mode of ventilation is used, tidal volumes may insidiously decrease as abdominal pressures increase. When minute ventilation decreases, hypercarbia will occur and hypoxemia can result from perfusion of the collapsed lung. These signs, hypoxia, hypercarbia, and increased plateau pressure, are nonspecific and their relation to increased intraabdominal pressure may not be appreciated [19]. Among patients with ARDS, elevated peak inspiratory pressures and plateau pressures can be misinterpreted as being caused by worsening ARDS rather than evolving ACS.

Renal Failure

Renal dysfunction commonly occurs in ACS. The challenge in diagnosis is that acute renal failure is also common in the critical illnesses associated with ACS including sepsis, pancreatitis, and burns. Therefore, oliguria from ACS can easily be attributed to other factors.

Increased abdominal pressure leads to decreased renal venous flow. Ultimately, this decreased renal venous flow causes ischemia, tubular dysfunction, and oliguria. Decreased cardiac output from ACS may also contribute to acute renal failure. In a study of healthy volunteers, IAH, as measured by gastric pressure, was generated by an external binder,
positive pressure ventilation, or by both methods. Ultrasound was used to assess renal arterial resistance and it significantly increased with IAH [20]. Dalfino et al. [21] measured intravesicular pressure in consecutive critically ill patients, and found that IAH greater than 12 mm Hg was predictive of acute renal failure, although other studies in postoperative patients have found a higher intraabdominal pressure (mean 27 mm Hg) is associated with acute renal failure [22].

Further compounding the problem is the kidney’s physiologic responses to decreased perfusion. Antidiuretic hormone (ADH) is released and the renin–angiotensin pathway is activated leading to reabsorption of sodium and water. The increase in serum ADH has been confirmed in human studies. Among patients undergoing laparoscopic donor nephrectomy with a pneumoperitoneum of 12 mm Hg, serum ADH levels were increased from the patient’s preinsufflation baseline as well as from open nephrectomy controls [23]. Increased water and sodium reabsorption may lead to further third space fluid volume and edema, and further increase IAH.

**Cardiovascular**

The cardiovascular effects of increased intraabdominal pressure are numerous. Thoracic and intraabdominal volumes are interrelated. As the abdominal pressure and abdominal volume increase, the diaphragm pushes cranially. The thoracic volume is subsequently decreased and this leads to increased intrathoracic pressure. In experimental models, the transmission of IAH to the thoracic cavity has been estimated to be around 50% [24]. Cardiac dysfunction and decreased output occur because of the effects on preload, contractility, and afterload.

Increased intrathoracic pressure leads to decreased inflow from the IVC and subsequently decreased cardiac preload. The elevation of the diaphragm also reduces the size of its caval opening and can constrict the IVC that further decreases venous return [25]. Parameters that have been commonly used to assess cardiac function and volume status for the critically ill may be unreliable in patients with IAH/ACS. For example, bedside ultrasound to assess the IVC size and collapsibility has been used to determine volume responsiveness [26]. This parameter may no longer be useful to assess volume responsiveness as inferior venal caval dimensions can be altered by IAH [20].

Pulse pressure variability and stroke volume variation have been used to predict patient responsiveness to volume loading. However, limited evidence suggests that the predictive ability of these parameters may be reduced in the presence of IAH/ACS. In an IAH animal model, stroke volume variation was no longer found to be predictive of responsiveness. Pulse pressure variability remained predictive if >20.5% rather than the
Contractility of both the right and left ventricles can be impaired by IAH as well. With increased thoracic pressure and decreased thoracic volume, pulmonary arterial pressures can increase. The rise in pulmonary pressures can be large enough to cause significant increases in right ventricular afterload. The combination of reduced venous return and increased pulmonary vascular resistance can cause right ventricular failure. Due to ventricular interdependence, compromised right ventricle function can impair left ventricular function [28]. In humans, decreased left ventricular function has been noted on transesophageal echocardiography when IAH is caused by intraabdominal insufflation during laparoscopic surgery [29].

Not only can preload and contractility decrease, but an increase in afterload can occur, further impairing blood flow. Afterload increases result from two mechanisms. First, vascular resistance increases directly from increased thoracic pressure on the aorta and pulmonary vessels as well as direct pressure on the intraabdominal organs from IAH. Second, due to decreased cardiac output, there is the resultant increase in systemic vascular resistance.

**Neurologic**

The systemic effects of IAH are not just limited to the abdomen and chest, but also affect the central nervous system. As discussed previously, the intracranial compartment is a fixed space in adults. Inside this enclosed space are the brain parenchyma, cerebral spinal fluid, as well as the venous and arterial blood supply. Any increase in one of these components increases intracranial pressure. IAH appears to cause increased intrathoracic venous pressure that leads to elevated jugular venous pressure. The higher jugular venous pressure leads to decreased venous outflow and a rise in intracranial pressure.

Animal model data support this hypothesis. In a swine model, Bloomfield et al. measured intraabdominal, intrapleural, external jugular venous, and intracranial pressures as an abdominal balloon was inflated with saline. As IAH occurred, pleural pressure increased along with external jugular venous and intracranial pressure. Intracranial pressure was decreased with either desufflation of the intraabdominal balloon or via median sternotomy [30].

This relationship is also borne out in humans. An observational trial in trauma patients with intracranial monitors measured intraabdominal,
central venous, and internal jugular venous pressures. Placement of a 15-L fluid-filled bag externally on the abdominal wall simulated increased IAH and resulted in statistically increased intracranial pressures. Temporally, pressures increased with the placement of a 15-L bag on the abdominal wall; however, the increase did not have a linear correlation between intrathoracic and intracranial pressures [31]. These findings have been confirmed in nontraumatic neurologically impaired patient populations [32] as well as in case reports of decompressive laparotomy for relieving ACS with concomitant reduction in measured intracranial pressure [33].
TREATMENT OPTIONS

Medical Management

Management strategies for ACS depend on the etiology and vary with the clinical scenario. While many recommendations exist, the clinical context is important and should be individualized to the patient.

To reduce intraabdominal pressure, the patient should have a functional nasogastric tube to decompress the stomach. A nasogastric tube is particularly important when small bowel ileus is the primary cause of IAH. If the patient has Ogilvie syndrome, or a paralytic ileus of the colon, a rectal tube, colonoscopic decompression, or neostigmine should be considered. A urinary indwelling catheter should also be in place, not only for monitoring of intraabdominal pressures and urine output, but also to decompress the bladder and to reduce the abdominal volume.

Negative fluid balance has been proposed as a useful method to reduce intraabdominal pressures. Diuresis has become an important part of the armamentarium. This treatment has not been specifically assessed in any clinical trial. Continuous venovenous hemodialysis and slow extended daily dialysis has been studied in a small series. In a study of nine patients with heterogeneous cause of critical illness, intraarterial pressure (IAP) decreased by a statistically significant difference but only from 12 to 10 mm Hg with volume removal [34]. With such limited data, no recommendation regarding hemodialysis was made by the World Society of Abdominal Compartment Syndrome [1].

Drainage of intraabdominal fluid collections is also an important adjunct in selected patients. Ascites can develop from liver failure, severe pancreatitis, or massive volume resuscitation. Hemorrhage and resultant clot formation is difficult to percutaneously drain. A study of nine patients with greater than 40% total body surface area burns who developed IAH/ACS from large volume resuscitation examined the efficacy of percutaneous drainage. Five required percutaneous drainage only and four failed percutaneous drainage and underwent decompressive laparotomy. In the percutaneous drainage-only group, 38 ± 28 mL per kg of fluid were drained by the catheter and 45 ± 20 mL per kg were removed initially in the percutaneous/decompressive laparotomy group. The author’s conclusions were that drainage is a viable technique as no patient experienced any complications directly related to the percutaneous drainage [35]. In an observational matched case–control trial, 31 surgical ICU patients who had percutaneous treatment of IAH were compared with patients who had decompressive laparotomy.
Bedside ultrasound was used to identify IAH/ACS patients with free fluid and to place a 14 French catheter under visualization. The IAH/ACS etiology was heterogeneous and included trauma (23%), burns (29%), postoperative (36%), and sepsis (12%) patients. Percutaneous drainage was successful for 81% of the patients with the remaining 19% of the patients requiring a decompressive laparotomy. Important predictors of failure of percutaneous drainage were drainage of less than 1,000 mL via the catheter and failure to reduce measured intraabdominal pressure by 9 mm Hg. It is important to note that during the study time period, decompressive laparotomy was performed for ACS in 265 patients. Therefore, percutaneous drainage was appropriate for a minority of patients [36].

Given that the abdominal cavity is not completely rigid, another medical management technique may include increasing the abdominal volume by relaxing the abdominal musculature with heavy sedation and neuromuscular blockade. De laet et al. performed a prospective cohort study, assessing the effect of neuromuscular blockade on nine patients with IAH. A single dose of cisatracurium reduced IAH from 18 to 14 mm Hg at 15 and 30 minutes, respectively [37].

Surgical Management

Decompressive laparotomy remains the standard of care when medical therapies fail. However, the mortality remains as high as 50% despite surgical decompression [38]. The mortality remains elevated as ACS is usually not the primary cause of the patient’s critical illness. Furthermore, abdominal pressure remains elevated when measured after decompression [38]. Pulmonary and cardiac parameters improve but do not normalize. Additionally, ACS has been described in spite of the abdomen remaining open [39]. Vigilance is therefore still required after surgical decompression and it would seem prudent to continue to monitor abdominal pressures. Decompressive laparotomy is not without risks. Enterocutaneous fistula, intraabdominal abscesses, and organ failure are associated with an open abdomen [40]. The inability to close the abdominal wall may lead to a large ventral hernia.

After laparotomy, a variety of techniques have been employed for coverage of the abdominal viscera to prevent the development of entero-atmospheric fistulae, control fluid losses, and allow re-exploration. One of the easiest methods is to close the skin while leaving the fascia open beneath. Towel clips have been previously used as well as suturing the skin close. These techniques are quick and inexpensive but do not expand
the abdomen volume well enough. Recurrent ACS is frequent.

Other techniques include repurposing sterile equipment as a temporary cover of the abdominal viscera. Sterile 3-L infusion bags or the Bogata bag are used by some centers. The use of sterile plastics covers for radiology cassettes has been described [41]. The drawback to these techniques is that peritoneal fluid loss is not well controlled.

Negative pressure wound therapy is now commonly employed. While there are commercially available products and suction devices, standard operating room equipment can be fashioned into a system. The benefit of this technique is that it (1) prevents the intraabdominal viscera from becoming adherent to the abdominal wall; (2) the negative pressure controls and removes fluid; (3) the negative pressure may prevent fascial retraction allowing for easier delayed abdominal wall closure; (4) dressing changes can be performed every 3 to 4 days simplifying wound management. However, cost remains a major drawback. Reported delayed closure rates vary widely in the literature.

Abdominal closure can be facilitated by placing tension on the fascia to prevent fascial retraction [42]. Protocols that specify scheduled re-exploration and partial closure with each trip to operating room has been advocated and their use has been associated with abdominal wall closure rates up to 100% [43]. Sequential closure, however, typically requires a week or more and multiple operations. Other techniques to obtain closure include acute component separation, or planned hernia with delayed component separation. Component separation closure is considered an important technique to electively repair hernias. This technique has not been studied for acutely ill patients who are not medically optimized and likely malnourished. The failure of component separation in the acute setting makes this method unavailable in the future for that patient when it would likely be successful. Current recommendations are to reserve component separation for elective repairs for medically optimized patients [44]. If the decision is to allow the patient to have a large abdominal wall hernia, coverage of the abdominal viscera with a split thickness skin graft or skin-only closure will usually be required.
PREVENTION

Prevention of ACS is an important strategy. Damage control resuscitation has been advocated for trauma patients. Among these patients, low normal blood pressure is permitted and over-resuscitation avoided. This concept emphasizes early control of hemorrhage, transfusion of blood and blood products, and reduced administration of crystalloids [45].

The type of fluid as well as the volume infused may prove consequential in secondary compartment syndrome. The use of albumin has been examined for burn patients. While a single-center study showed no change in the occurrence of ACS by including albumin along with crystalloids in burn resuscitation [46], another prospective study showed decreased intraabdominal pressures [47]. A meta-analysis suggested albumin use decreased the occurrence of all compartment syndromes but this study did not differentiate between the types of compartment syndromes [48]. The use of fluid types other than crystalloids as well as other patient populations and fluid effects on the development of ACS is unclear.

Damage control surgery and deciding not to close the abdomen at the index operation is also an important part of prevention. Data here is sparse. For trauma patients, major liver injury or any other injury requiring packing for hemostasis is one consideration. The occurrence of ACS was reduced from 80% to less than 24% in a retrospective cohort trial of severely injured trauma patients [49]. A small series examined the outcomes of 27 patients with a ruptured abdominal aortic aneurysm who were repaired by the open technique. In a retrospective analysis of patients who remained intubated postoperatively and had shock, colonic ischemia and ACS occurred only those patients with IAP of 21 mm Hg or higher [50]. The limitation of course is that the IAP was monitored postoperatively. Current societal recommendations for trauma and emergency surgery patients suggest the following intraoperative markers to consider leaving the abdomen open: large volume resuscitation defined as transfusion of greater than 10 units of packed red blood cells or the administration of greater than 15 L of crystalloid. Other factors to consider include hypothermia (temperature less than 35°C) and acidosis with a pH <7.2 [51].
CONCLUSIONS

Abdominal hypertension and ACS are common among surgical and medical patients, have significant detrimental physiologic effects, and are associated with an increase in mortality. Many risk factors for the development of IAH and ACS have been described. Selection of particular patients for intravesicular pressure monitoring remains unclear. The accuracy, feasibility, and low cost of intravesicular pressure monitoring should make unrecognized IAH/ACS uncommon. The many medical and surgical treatments available should be tailored to the individual patient. Decompressive laparotomy, however, remains the most common treatment option for ACS with organ dysfunction.
REFERENCES

1435, 2011.

Up to 300,000 women died worldwide in 2015 as a result of pregnancy-related conditions [1]. Maternal mortality has been decreasing each year since 1990, with the greatest reductions in these deaths coming in developed countries. However, the overall rate in the United States has increased [2]. In 2013, the maternal mortality ratio was 18.5 per 100,000 live births, an increase of 1.7 percent from the rate of 1990 [3]. It is unknown if this difference is due to an improvement of identifying and coding for pregnancy-related deaths [4], or if it should be attributed to increases in maternal age, body mass index, and comorbidities. The leading cause of maternal mortality in the United States is cardiovascular disease and cardiomyopathy. Other common causes of mortality include thromboembolic events, hemorrhage, infections, and amniotic fluid embolism [5]. It is not surprising that, because the intensive care unit (ICU) is a common setting for care of these patients, both maternal and fetal mortality are high when a pregnant patient is admitted to the ICU [6].

This chapter will review the maternal anatomic and physiologic adaptations to pregnancy, considerations of potential fetal harm from diagnostic studies or medication administration, and specific pregnancy disease states that may complicate the care of the critically ill pregnant patient such as preeclampsia, eclampsia, obstetric hemorrhage, and trauma. Specifics related to the diagnosis and treatment of respiratory failure and other common medical problems in pregnancy is discussed elsewhere in the text (Chapter 164).
MATERNAL PHYSIOLOGIC ADAPTATIONS TO PREGNANCY

Cardiovascular System

The cardiovascular system undergoes significant alteration during pregnancy. The major changes seen include an increase in cardiac output, blood volume expansion, and reductions in systemic vascular resistance and blood pressure (BP). These changes start early in the first trimester, peak in the second trimester, and remain constant until delivery [7]. Hemodynamic changes surrounding labor and delivery are also significant.

Cardiac output rises up to 50% above baseline during pregnancy, with half of this rise coming in the first trimester. Cardiac output increases by several mechanisms including: (1) increasing preload (rise in blood volume), (2) decreasing afterload (decrease in vascular resistance) and (3) a rise in heart rate [8]. Initially, the increase in cardiac output comes from the rise in stroke volume, and later in pregnancy, heart rate is the major factor. Ejection fraction stays constant throughout pregnancy. This increase in workload can cause heart disease in women to decompensate during the later part of pregnancy. Both plasma volume and red blood cell mass expand during pregnancy; however, there is greater plasma expansion than red blood cell production, resulting in a physiologic anemia of pregnancy [9]. Both systolic and diastolic BPs fall early in pregnancy and average 5 to 10 mm Hg below baseline. In the third trimester, BP normalizes [10]. The drop in BP is induced by a reduction in systemic vascular resistance, the mechanism of which is not completely understood, though both are likely to be hormonally and placentally mediated.

Respiratory Adaptations

The respiratory tract undergoes profound changes during pregnancy. Progesterone is a known stimulant of both respiration and respiratory drive [11]. A relevant hyperventilation therefore occurs in pregnancy. Minute ventilation rises almost 50% by term, largely secondary to an increase in tidal volume [12]. Functional residual capacity decreases by 20% due to an upward shift of the diaphragm. Expiratory reserve volume and residual volume also decrease. However, inspiratory capacity increases, resulting in only minimally decreased total lung capacity [13]. There is an increase in PaO₂ and a decrease in PaCO₂ levels. This respiratory alkalosis leads to a compensatory excretion of bicarbonate by
the kidneys, resulting in a relatively normal pH (7.4 to 7.45) [14]. Measurements of pulmonary function and disease should be interpreted in the context of the above changes [15].

Hematologic Adaptations

As stated previously, plasma volume during pregnancy increases by 50% from prepregnancy levels. The red cell mass will increase to a lesser degree. This phenomenon has been termed the physiologic anemia of pregnancy [16,17].

Increased catecholamine and steroid levels during pregnancy cause a demargination of mature leukocytes from the endothelium. This leads to a physiologic leukocytosis of pregnancy, with the white blood cell count increasing by 5,000 to 10,000 cells per mL [16,17].

Pregnancy is associated with changes in several clotting factors (resistance to activated protein C, decreases in protein S, increase in factors I, II, V, VII, X, and XII). This results in a reduction in prothrombin and partial thromboplastin times [18,19]. The net effect is the production of a hypercoagulable state. Venous thromboembolism occurs more frequently during pregnancy and presents a three to fourfold higher risk in the peripartum period than during pregnancy [20].

Renal Adaptations

Normal pregnancy provides both anatomic and functional changes to the renal system. The kidneys increase in size by 1 to 1.5 cm. The renal pelvises and calyces may be dilated and hydronephrosis and hydroureter may be seen in up to 80% of women [21]. Glomerular filtration rate (GFR) rises markedly during pregnancy, due to increases in cardiac output and renal blood flow. This results in a decrease in serum creatinine concentration. Among pregnant women with a normal serum creatinine at baseline, the creatinine may remain within the normal range despite a significantly reduced GFR. A small rise in serum creatinine usually reflects a marked reduction in renal function. Hence, careful attention to small fluctuations of serum creatinine is required to detect renal injury during pregnancy (Table 53.1).

When caring for any critically ill patient, diagnostic imaging is critically important. When the patient is pregnant, care must be taken to weigh the risk of the imaging study with the potential change in management given the outcome of that study.

It is important to remember that there are no studies of humans to evaluate the risk of radiation. Most evidence is case reports and data from survivors of nuclear bombings/accidents [22,23].

There are four areas of potential harm when assessing radiation exposure: pregnancy loss, fetal malformations, disturbances of growth/development, and carcinogenic effects. The effect radiation will have on a fetus depends on the gestational age at the time of exposure and the dose of radiation that the fetus is exposed to.

The majority of diagnostic procedures expose the fetus to less than 0.05 Gy of radiation. There is no evidence that this level of exposure increases the risk of fetal anomalies, disability, growth restriction, or pregnancy loss at these levels; however, these low levels may increase the risk of childhood leukemia [24,25]. The threshold at which a fetus sustains risk is not completely known, though evidence suggests that the risk of malformations increases at doses greater than 0.1 Gy.

The timing of exposure is also important. The fetus is most sensitive to radiation exposure early in pregnancy. In early pregnancy, the “all or none” phenomenon applies, which means that the fetus either survives intact or is resorbed. This is true for the first 14 days after conception [26]. After the first 14 days, an embryo can be damaged. In the first trimester, the most common abnormalities seen are growth restriction or central nervous system abnormalities [27]. Radiation levels needed for these mutations are 0.1 to 0.2 Gy prior to 16 weeks and 0.5 to 0.7 Gy after 16 weeks of gestation [28]. Growth restriction usually is not seen until >1 Gy. After 20 weeks, the fetus is resistant to the teratogenic effects of radiation [29].

There are no known fetal effects from exposure to ultrasound or magnetic resonance imaging (MRI). MRI examinations are used as an adjunct to ultrasound in the second and third trimesters to aid in the diagnosis of certain fetal anomalies. Contrast agents should be avoided during the first trimester [30,31].

If a significant alteration in management is to be undertaken as a result of the information obtained from the procedure, the potential fetal risk should be considered. If excessive radiation doses to the pelvis are administered inadvertently, it is important to calculate the fetal isodose radiation exposure. An excess of 10 cGy delivered to the fetus may lead to
significant fetal effects. Table 53.2 outlines both the amount of radiation of common imaging studies and the potential fetal effects of radiation exposure.

MEDICATIONS AND PREGNANCY

Analgesic Agents

Opiate narcotic agents administered for short periods of time have been shown to be safe during pregnancy. They have shown no adverse fetal effects. Chronic opiate use during pregnancy has been associated with intrauterine growth restriction and neonatal abstinence syndrome [32]. Nonsteroidal antiinflammatory agents may decrease fetal renal blood flow, leading to oligohydramnios. They also will lead to the in utero closure of the ductus arteriosus, producing fetal pulmonary hypertension after 32 weeks of gestation. Short courses of indomethacin may be used with caution prior to 32 weeks of gestation.

Antibiotics

Penicillins, cephalosporins, erythromycin, clindamycin, and vancomycin are considered safe during pregnancy. There is some concern regarding renal toxicity with vancomycin. Aminoglycosides have been implicated in fetal ototoxicity [33]. However, only streptomycin and kanamycin have been implicated. Gentamicin has not been reported to have significant ototoxicity and is used commonly during pregnancy. Sulfonamides compete with bilirubin-binding sites and may lead to neonatal kernicterus if administered during the third trimester. Tetracycline is teratogenic, leading to brown teeth and abnormal long bone development [33–35] (Table 53.3).

Sulfa drugs: OK in second trimester, risk of birth defects in first trimester, and kernicterus in third trimester

Fluoroquinolones: toxic to cartilage development

Anticoagulants

Unfractionated heparin, because of its molecular size and ionic negative charge, has been shown not to cross the placental membrane [36]. Therefore, it is the anticoagulant of choice in all trimesters of pregnancy and may be used with relative fetal safety. Fractionated heparins also have been shown not to cross the placental membrane. They may be used throughout pregnancy as well. If fractionated heparins are used during pregnancy, it is advised to change to unfractionated heparin late in the third trimester because when surgical intervention is needed, unfractionated heparin may be reversed with protamine sulfate and because regional anesthesia can be used after reversal [37]. Warfarin and its derivatives are contraindicated during the first trimester as these agents are teratogenic, producing midline defects such as clefts, cardiac septal defect, and limb bud abnormalities. In all trimesters, warfarin crosses the placenta and may lead to spontaneous fetal bleeding [38–40]. In some selected cardiac patients (particularly those with mechanical valves), warfarin may be used during the second and early third trimesters. Fetal intracranial bleeding has been observed with warfarin use during the late third trimester.

Antihypertensives

Pregnant patients will require acute antihypertensive intervention when the systolic BP exceeds 160 mm Hg or the diastolic BP exceeds 110 mm Hg. Preservation of the fetal circulation must be kept in mind when treating these conditions. For the acute management of hypertensive crisis in pregnancy, labetolol or hydralazine are recommended [41,42]. Hydralazine is dosed as 10 mg IV push. Labetolol is given as a 10-mg dose IV, followed by a 20-mg dose at 10 minutes if no response is observed. If still no response in BP is observed, the dose may be increased to 40 mg in 10 minutes and followed by 80 mg in 10 minutes. The 80 mg dose may be repeated one time. The total dose should not exceed 220 mg [43,44].
Angiotensin-converting enzyme inhibitors and angiotensin receptor blocker agents are contraindicated during pregnancy. They have been associated with fetal anomalies and intrauterine fetal death secondary to fetal cardiovascular collapse.
SPECIFIC PREGNANCY DISORDERS

Hypertensive Disorders of Pregnancy

Preeclampsia is most commonly defined as hypertension (>140/90) in combination with proteinuria (>300 mg per day) beginning after the 20th week of pregnancy in a previously normotensive person. Eclampsia is defined as meeting the criteria for preeclampsia with the addition of seizures. Preeclampsia and eclampsia are multisystem diseases that develop only during pregnancy or, more rarely, during the postpartum period. Previously, preeclampsia was defined as mild or severe. In 2013, the American Congress of Obstetrics and Gynecology changed the categories; preeclampsia is now defined as being “with” or “without” severe features. Severe features are defined as BP >160/110 mmHg, or evidence of end organ disease. They also removed proteinuria as an essential criterion for diagnosis of preeclampsia with severe features and removed massive proteinuria (5 g per 24 hours) and fetal growth restriction as possible features of severe disease [45].

The underlying cause of preeclampsia is not fully understood, but likely involves maternal, fetal, and placental factors. Abnormalities of blood vessel development can result in placental underperfusion, hypoxia, and ischemia [46]. The severity of disease is influenced not only by maternal and placental factors but also likely by paternal and environmental factors [47].

It is the complications of preeclampsia that usually indicate ICU admission. Sequelae include refractory hypertension, neurologic manifestations (seizure, intracranial hemorrhage, and elevated intracranial pressure), renal failure, liver failure or rupture, pulmonary edema, HELLP syndrome, or disseminated intravascular coagulation (DIC) [6].

Management

Though all of the complications of preeclampsia can be treated, the ultimate treatment for preeclampsia is delivery. If a patient who develops preeclampsia is near term, prompt delivery is the recommendation. Patients who are preterm without evidence of severe features can be managed expectantly with close monitoring until term gestation is reached (37 weeks) or severe features develop. For selected patients remote from term with severe features, expectant management can be undertaken at a tertiary care center [45]. Patients remote from term should be given steroids to enhance fetal pulmonary maturity. Patients
with severe features should be treated with IV magnesium. It has been shown to be superior to other antiepileptics for the prevention of seizure activity \[48,49\]. Magnesium is given as a 4-g bolus IV over the first hour, then at 2 g per hour until 24 hours post delivery with monitoring of reflexes and magnesium levels.

ICU care involves managing the complications of preeclampsia:

1. **Severe hypertension**: BP greater than 160/110 mmHg is generally treated with IV antihypertensives. Labetolol and hydralazine are the drugs of choice \[50\]. Exact dosing is the same as the algorithm above.

2. **Seizures**: Eclamptic seizures are treated with IV magnesium. In cases unresponsive to magnesium, benzodiazepines may be used. When the seizure activity persists, the next agent of choice is phenytoin. In severe refractory cases, muscle paralysis with general anesthesia and ventilatory support may be needed \[48\].

3. **DIC**: Treatment of DIC involves identifying the underlying cause. Placental abruption is a common cause among those with preeclampsia. Aggressive resuscitation with blood products to reverse coagulopathy is sometimes needed.

4. **Pulmonary edema**: Pulmonary edema may present with dyspnea or acute respiratory failure. Supportive management includes supplemental oxygen and fluid restriction. Diuresis is indicated when there is fluid overload, although this is rare because most patients are volume depleted.

**Obstetrical Hemorrhage**

Vaginal bleeding during pregnancy is a common event. The source of the bleeding is almost always maternal. The evaluation, differential diagnosis, and management of bleeding differ by trimester and volume. Vaginal bleeding during the third trimester can be a medical emergency. When significant hemorrhage occurs, prompt medical or surgical intervention is needed.

**Antepartum Hemorrhage**

The most common cause of bleeding during the first trimester is miscarriage. Miscarriage is common (up to 25% of pregnancies), and significant bleeding requiring transfusion, while rare, does occur \[51\]. Another less prevalent (~2% of pregnancies) cause of hemorrhage during the first trimester is ectopic pregnancy. Rupture of an ectopic pregnancy can be a life-threatening emergency and aggressive monitoring of hemodynamic status, fluid resuscitation, and administration of blood
products may be required. Vaginal bleeding in the second and third trimester is less common but may be a medical emergency dependent on etiology; the possibilities are described below.

**Placenta Previa**

Placenta previa is defined as the placental tissue extending to or covering the cervical os. This diagnosis is uncommon, occurring in ∼4/1,000 births [52], but the sequelae of this condition has the potential for severe bleeding. Classically, the patient with placenta previa will resent with painless vaginal bleeding; however, some women will present with pain or contractions in association with bleeding [53,54]. Any woman without an ultrasound documenting placental location who presents with bleeding should undergo ultrasound evaluation for placental location. Ultrasound should be performed prior to digital examination of the cervix to avoid palpation of the placenta and severe hemorrhage.

Women with placenta previa are at increased risk of hemorrhage during the antepartum, intrapartum, and postpartum periods [55]. They are therefore more likely to undergo blood transfusion, peripartum hysterectomy, uterine artery embolization to have a placenta accreta [56]. Maternal mortality secondary to previa is low in resource-rich countries; however, in the third world, this remains a high risk of maternal mortality [56]. Because the risk of severe bleeding and emergent, unscheduled delivery outweigh the risks of late preterm birth, delivery of patients with known previa is recommended by cesarean section between 36 and 37 weeks of gestation [57,58].

Though an actively bleeding placenta previa is a potential emergency, most cases of acute bleeding are self-limited. Patients should be admitted, a complete blood count and Type and Screen should be sent. Fetal monitoring should be employed. If the bleeding is active, both the mother and fetus should be closely monitored and supportive care provided. Indications for emergent cesarean delivery include refractory, life-threatening hemorrhage, non-reassuring fetal status or a significant bleed after 34 weeks of gestation. If the bleeding episode is self-limited, the patient can be monitored in the hospital. A course of antenatal corticosteroids should be given for fetal benefit given the potential for preterm delivery. If the patient is Rh negative, Rhogam should be given. When delivery is undertaken, close coordination and planning with anesthesia should be undertaken as the presence of previa increases the risk of hemorrhage and placenta accreta and percreta.
Abruption Placenta

Placental abruption is the premature separation of the placenta from the uterus (prior to the delivery of the infant). Abruption occurs in up to 1% of pregnancies and may be small and not clinically significant or may lead to severe life-threatening bleeding and DIC.

The clinical presentation of abruption is vaginal bleeding with associated uterine pain or contractions. There may or may not be associated fetal distress. In severe cases, DIC and coagulopathy occur. The bleeding may be vaginal or confined to the uterus, so the amount of vaginal bleeding is not a reliable indicator of severity. Ultrasound is not a reliable indicator of abruption (only 2% of abruption can be visualized on ultrasound). If coagulopathy occurs, resuscitation with blood-replacement products such as fresh-frozen plasma or cryoprecipitate should occur [59]. The definitive management is delivery and resuscitation. If the patient is preterm and the abruption is limited and fetal status is not affected, potential inpatient surveillance can be undertaken. Antenatal corticosteroids are given for fetal lung maturity.

Postpartum Hemorrhage

Significant hemorrhage postpartum occurs among 2% to 5% of deliveries. The most common cause is uterine atony. Other causes include retained products of conception, lacerations of the cervix and vagina, and unrecognized coagulopathies [60]. Blood loss of more than 500 mL at vaginal delivery or 1,000 mL at cesarean section is classified as postpartum hemorrhage. Delayed hemorrhage, 3 to 7 days postpartum, most often is due to retained placental fragments or unrecognized congenital coagulopathies [60].

The initial assessment should include a determination of the cause of hemorrhage. Careful examination of the cervix and vagina to assess for unrecognized lacerations is warranted. Manual exploration of the uterus is performed both to assess tone and to apply uterine massage if atony is noted. If uterine atony is encountered, uterotonics are given. Pitocin (oxytocin) is usually first line and is given IV with 20 to 40 units mixed in IV fluids [60–62].

If uterine atony persists, several other uterotonics may be given. Methergine, misoprostol and Hemabate may all be used and the order in which they are used does not appear to be important. Methergine is an ergot derivative. It is given as 0.2 mg IM and is contraindicated for patients with hypertension, as significant elevations in BP may occur. Hemabate and misoprostol are prostaglandins. Hemabate is given as 250 µg IM [63]. Misoprostol is given rectally at 400 to 800 µg. Hemabate may cause significant bronchospasm and is contraindicated for patients with
If medical management of postpartum hemorrhage is unsuccessful, surgical intervention is needed. An intrauterine examination under anesthesia for retained products and dilatation and uterine curettage may be performed. If still unresponsive, uterine artery embolization may be attempted. In cases of unresponsive atony, laparotomy and uterine-constricting b-lynch suture may be performed. If all measures have failed to resolve the bleeding, hysterectomy may be employed as a last resort [64–66].

Amniotic Fluid Embolism

Amniotic fluid embolism is an extremely rare event. Incidence is 1 to 12 cases per 100,000 deliveries [67]. Clinically, patients present with sudden onset of cardiovascular and respiratory collapse at or around the time of delivery [68]. When amniotic fluid enters the intervacular space, vasoactive and fibrinolytic components precipitate cardiovascular collapse and respiratory failure. Immediate identification and aggressive treatment is required. Despite this, mortality rates are still as high as 50% [69].

Intubation and mechanical ventilation with positive end-expiratory pressure is employed. Inotropic and vasoconstrictor agents are needed for cardiac and vascular support. Invasive right-sided cardiac monitoring is also indicated. These patients will often experience a rapid and fulminant DIC, requiring resuscitation with fresh-frozen plasma and cryoprecipitate. These patients require intensive monitoring and support. Extra corporeal membrane oxygenation has been used to rescue patients with refractory cardiorespiratory collapse. If the patient survives the initial insult, most will survive [70,71].

Trauma Complicating Pregnancy

Trauma is the most common cause of death during pregnancy not related to obstetric factors. Motor vehicle accidents and domestic violence make up the majority of cases; however, there are many other potential causes of trauma. Though trauma is a common occurrence during pregnancy, less than 1% will require hospitalization [72].

The physiologic alterations of pregnancy are discussed in detail above. Because of these, particularly the increased blood volume, the pregnant trauma patient is less likely to immediately manifest signs of shock. The abdominal position of the uterus in the third trimester makes this organ more susceptible to both blunt and penetrating trauma. As the uterus grows, the bladder is pulled superior and rendered more susceptible to traumatic injury in pregnancy.
Motor vehicle accidents account for 60% of injuries in pregnancy. The pregnancy outcome is directly related to the severity of maternal injuries. The most common cause of fetal death is maternal death [73,74].

Following blunt injury secondary to a motor vehicle accident, placental abruption is the most common complication associated with the pregnancy. Placental abruption occurs among 2% to 4% of patients with these injuries. Ultrasound to detect placental abruption is not sensitive, as stated above [74–76]. Contraction monitoring with a tocometer has a high negative predictive value for abruption and most abruptions will occur during the first 4 to 8 hours postinjury. No consensus exists as to the length of the post-trauma monitoring interval, but at least 4 hours is recommended [77,78]. Rarely, a delayed abruption up to 48 hours postinjury may occur. There is no sensitive test to predict delayed abruption. However, if fetal–maternal hemorrhage is observed, the incidence is higher. Patients can be screened with a Kleihauer–Betke assay to assess for fetal–maternal bleeding [79]. If positive, a longer period of observation may be indicated. As small amounts of fetal blood may enter the maternal circulation, all patients require blood type and screen, and Rh-negative patients should receive Rhogam. Continuous fetal monitoring should occur. The usual markers of severity of maternal illness—BP, heart rate, hematocrit, and arterial partial pressure of carbon dioxide—are not predictive of fetal outcomes. Imaging studies with ultrasound are the first line for assessment. In the second and third trimesters, computed tomography scans of the abdomen and pelvis may be undertaken when indicated. In severe cases, cesarean section may improve maternal outcomes, by removing the placental arteriovenous shunt [80]. Potential maternal lifesaving cesarean delivery can be performed at ~4 to 5 minutes into maternal code to attempt to remove placental blood flow.

**Penetrating Trauma**

Penetrating injuries of pregnant patients most commonly are gunshot wounds or knife wounds. Pregnant patients have a better prognosis after penetrating abdominal trauma as the large muscular uterus protects maternal vital organs. Maternal visceral injuries complicate 19% of penetrating abdominal trauma with a 3.9% maternal mortality rate [81]. The anterior and central location of the uterus subjects the fetus to significant risk from penetrating wounds. The fetus is injured in 66% of these cases, with a high 40% to 70% fetal mortality rate [82]. The management of these injuries remains controversial. Many experts
advocate surgical exploration. Conservative management with imagining and observation may also be considered. A coordinated effort between the trauma surgeon and obstetrician is important for achieving the best outcomes for both mother and fetus [81–83].

8. American College of Obstetricians and Gynecologists: ACOG committee opinion no. 560: medically indicated late-preterm and

Acute limb ischemia (ALI) occurs as a result of sudden inadequate arterial perfusion to an extremity. This state of hypoperfusion can result in a number of both local and systemic manifestations. These include loss of sensory and motor function of the affected extremity, gangrene leading to sepsis, as well as systemic acid–base disturbances and increased cardiopulmonary stress. Unfortunately, ALI also commonly develops in the setting of systemic illness and multiple other medical comorbidities. This is especially true in the intensive care unit (ICU) setting in which concomitant conditions such as myocardial infarction, hypercoagulable states, or hypotension requiring pharmacologic support play a role in both the etiology and disease progression [1]. Furthermore, revascularization can lead to ischemia–reperfusion injury impacting multiple organ systems and rhabdomyolysis as toxic by-products are reintroduced into the system circulation.

ALI is a devastating condition with 30-day mortality rates of 15%, and 5-year mortality rates of up to 50%. In addition, amputation rates range from 10% to 30% [2]. Due to its high rate of complications, ALI is a vascular surgery emergency necessitating expedient evaluation and treatment when indicated. This chapter reviews the etiology, evaluation, and management of both upper and lower extremity ALI of the critically ill patient.

1 These authors contributed equally to the content in this chapter.
ETIOLOGY

The most common causes of ALI are embolism and thrombosis. These two etiologies account for more than 90% of ALI cases [3,4]. Less common etiologies include aortic dissection and low flow states secondary to poor cardiac output. Embolic events typically originate from a cardiac source. The most common condition associated with cardiac emboli is atrial fibrillation but other cardiac sources include myocardial infarction leading to mural thrombus, valvular heart disease, and endocarditis [5,6]. Myocardial infarction and endocarditis are especially dreadful causes of ALI as these patients are extremely high-risk surgical candidates due to the coexisting medical comorbidities.

Less common causes of peripheral emboli include paradoxical emboli, aortic mural thrombus, and arterial atheroemboli. The presence of a patent foramen ovale allows the thrombus to traverse from the deep venous to arterial circulation leading to an ALI event. Paradoxical emboli should be suspected among patients with concomitant deep vein thrombosis and ALI without other cardioembolic risk factors [7]. Aortic mural thrombus typically presents as an asymptomatic finding and is commonly seen in the setting of hypercoagulable states such as malignancy or underlying aortic pathology. Atheroembolic events occur as a result of disruption of cholesterol plaque. This can be related to vessel manipulation from recent interventions such as cardiac or cerebral catheterizations, or peripheral vascular interventions. It can also be spontaneous in the setting of significant aortic atherosclerotic disease. Atheroemboli typically migrate to the distal vasculature, resulting in distal vessel thrombosis or blue toe syndrome [8]. This is in contrast to cardiac sources of emboli which typically lodge at arterial bifurcations due to the change in vessel caliber at these locations. Over half of cardioemboli occur in the iliofemoral arteries; the popliteal and brachial arteries are less common areas of embolization [9].

Thrombosis of native arteries or previously placed stents or grafts is an increasingly common cause of ALI. In situ thrombosis of native arteries occurs among patients with significant preexisting atherosclerotic disease burden. Most patients will have risk factors for peripheral arterial disease (PAD) and a portion will have a discernible history of claudication, rest pain, or nonhealing ulcers prior to their acute thrombotic event. Common sites of thrombosis correlate with the location of preexisting lesions;
these typically include the iliac or superficial femoral arteries \[10\]. Low flow states, hypercoagulability, and endothelial injury lead to disruption of atherosclerotic plaques and thrombus formation. This pathophysiology is exacerbated for the critically ill patient who suffers from cardiac compromise, sepsis, and vasopressor dependence. Critically ill patients exhibit elevated levels of inflammatory markers such as TNFα which has been shown to affect atherosclerotic plaque stability and increase the risk of thrombosis \[11\]. Critically ill patients also exhibit increased levels of procoagulant activity, especially in the setting of sepsis, heparin-induced thrombocytopenia, and disseminated intravascular coagulation \[12\]. These risk factors also have a significant impact on the patency of previously placed arterial stents or bypasses. Therefore, a detailed history of both endovascular and surgical revascularizations should be taken, as the presence of prior interventions will influence both the diagnosis and subsequent management.

Less common causes of ALI include arterial dissection, non-thrombotic limb ischemia secondary to low flow state, and traumatic arterial injury. Arterial dissection can occur spontaneously or as a result of iatrogenic injury secondary to arterial catheterization. Non-thrombotic limb ischemia often occurs in the setting of low cardiac output or vasopressor dependence. In these instances, the vessels remain patent; however, perfusion is limited by severe vasoconstriction at the arteriole and capillary level \[13\]. Blunt limb distraction injuries such as fractures and dislocations, or penetrating trauma from stabs or gunshot wounds, can lead to arterial injury. These can have a delayed presentation, so high-risk patients should be monitored with serial vascular examinations \[14\].

The etiology of an ALI event is critical for determining the subsequent evaluation and management. Patients who suffer embolic events typically do not have robust collateral peripheral circulation and can quickly develop permanent deficits if left untreated. On the other hand, thrombosis of native vessels is better tolerated due to the preexisting presence of collateral circulation in the setting of PAD. However, these patients often require more extensive revascularizations due to a heavier burden of underlying disease. Finally patients with non-thrombotic ALI secondary to low cardiac output or vasopressor dependence often improve with treatment of the underlying condition.
EVALUATION AND DIAGNOSIS OF ACUTE LIMB ISCHEMIA IN THE ICU POPULATION

A careful, detailed history and physical examination to elicit the etiology of ALI can have a tremendous impact on the overall management and prognosis for a patient. Assessment of the etiology, determining the extent of ischemia and neuromuscular damage, and establishing an appropriate treatment plan must be performed rapidly to minimize the time of ischemia. Patients in the ICU are often unable to provide necessary history and participate in a thorough examination; therefore, a thorough examination of their documented history and interviewing the family and critical care staff is often necessary to ascertain a complete picture. Medical records should be reviewed for key comorbidities including history of atrial arrhythmias, coagulation disorders, recent percutaneous interventions (i.e., cardiac catheterizations), history of claudication or rest pain, and previously lower extremity interventions should be investigated. Examining previous imaging including echocardiograms, computed tomography (CT) scans demonstrating aneurysmal disease or mural thrombus, and prior angiograms should be performed to understand possible etiologies or baseline disease.

A comprehensive physical examination is compulsory in order to determine the duration and extent of lower extremity ischemia; this will assist in deciding the appropriate management. To determine the diagnosis and duration of ALI, the six “Ps” of acute ischemia need to be evaluated—pain, paresthesias, pulselessness, pallor, poikilothermia, and paralysis. Bilateral lower extremities should be evaluated to determine if there are signs of underlying chronic PAD such as dependent rubor with elevation pallor, sparse hair growth, dystrophic nail growth, ulceration or nonhealing lesions, and lack of palpable pulses The extent of pallor, coolness, sensory and/or motor deficits, and mottling often indicates the level of arterial obstruction. Ischemic symptoms tend to occur one vascular bed distal to the level of obstruction—for example, mottling in the foot and calf implies an obstruction in the superficial femoral artery.

A careful pulse examination is a reliable method to determine the level of arterial obstruction. Bilateral pulse examination should be performed including the femoral, popliteal, dorsalis pedis, and posterior tibial arteries. When pulses are nonpalpable, continuous wave Doppler examination should be performed at the bedside. Assessing the quality of the pulse and the phasicity of the signal is important in assessing the severity of the occlusion; comparing the affected to the unaffected side is also important. Bedside ankle-brachial indices should be performed and
compared to the contralateral limb and to any baselines values on the affected limb. Additional signs can indicate the pathophysiology. A “water hammer” pulse will indicate pulsation against an obstruction such as a recent embolus or thrombus. Evaluating for pulsatility, a palpable thrill, or an audible bruit can indicate an iatrogenic pseudoaneurysm or arteriovenous fistula in the setting of recent percutaneous intervention such as central line, arterial stick, cardiac catheterization, or angiogram. Whether or not additional imaging is obtained will depend on the severity and acuity of the ischemia. Often a physical examination alone is enough to determine location of disease. If the patient is stable and the limb is not immediately threatened, additional imaging such as a CT angiogram can precisely identify the location of disease and define the arterial lesions in the affected limb. Duplex ultrasound can also be utilized, including at the bedside, to define suspected lesions. Such imaging should be readily available within a short timeframe and can be extremely helpful for operative planning. In cases where emergent revascularization is indicated and the burden of disease is not clear from clinical evaluation, a formal on-table angiogram in the operating room is a rapid way to define the pathophysiology and plan revascularization.
TREATMENT OF ACUTE LIMB ISCHEMIA IN THE ICU POPULATION

Treatment of ALI in the critical care population requires understanding of the etiology of the ischemia, the viability of the affected limb, and evaluation of the patient’s overall medical status.

The main treatment modalities of ALI can be divided into medical and operative management. Medical management includes systemic anticoagulation and supportive care. A heparin infusion, with a goal partial thromboplastin time (PTT) of 60 to 80, is the usual form of systemic anticoagulation that should be initiated immediately to prevent thrombus propagation. However, in the cases of heparin-induced thrombocytopenia or heparin allergy, a direct thrombin inhibitor, such as argatroban, can be used. In many instances of ALI in a critical care setting, these patients require multiple pressors for blood pressure support. Weaning pressors as tolerated, supporting intravascular volume, and placing the patient in a reverse Trendelenburg position to allow for the benefits of gravity, and utilizing a Bair hugger are all supportive measures that can be an effective adjuncts to systemic anticoagulation.

Treatment of ALI can be guided by the revised Rutherford Criteria proposed by The Society for Vascular Surgery and International Society for Cardiovascular Surgery (SVS/ISCVS) which stratifies levels of severity of ALI (Table 54.1). Category I, or viable, limbs have no sensory or motor deficits. These patients are appropriate for observation or systemic anticoagulation, possible angiogram and thrombolysis if appropriate. Category II limbs are the most difficult to differentiate, and are separated into two categories, IIa and IIb. Category IIa limbs are marginally threatened; they have minimal sensory loss and revascularization can be directed by expeditious angiography after systemic anticoagulation. Diagnostic imaging should be performed to guide treatment. Duplex ultrasonography, CT angiogram, or magnetic resonance angiogram are all excellent modalities to precisely identify the location and extent of the lesion and help plan intervention. Category IIb limbs are immediately threatened with both motor and sensory loss; if these patients do not undergo immediate operative revascularization, they are at a high risk of limb loss. The additional time needed to get additional imaging can put them at higher risk of limb loss and often they are taken directly to the operating room without additional studies. Category III limbs have sustained irreversible damage; these patients are often insensate with profound paralysis of the limb; primary amputation for pain control and avoidance of sepsis is the mainstay of therapy. Attempts at
Revascularization will not only fail to result in limb salvage, but can be hazardous and precipitate multiorgan system dysfunction due to severe ischemia–reperfusion injury.

For critically ill patients, their overall medical status is a guiding factor to determine if they are appropriate for revascularization. If the patient is hemodynamically unstable or experiencing profound cardiopulmonary or multisystem organ dysfunction, surgical revascularization or even aggressive endovascular revascularization might precipitate the patient’s demise. In these instances, revascularization should be delayed or deferred altogether to save “life over limb.” Systemic anticoagulation, ongoing observation, and conservative measures become the mainstays of treatment. In rare instances of category III limb ischemia, primary amputation of a densely ischemic or secondarily infected limb is necessary to prevent failure of other organs.
Open surgical revascularization offers the advantage of immediate reperfusion to the affected extremity. Surgical options are dictated by the level of arterial obstruction but generally include a combination of open surgical exploration with Fogarty balloon thromboembolectomy, thromboendarterectomy with patch angioplasty, and bypass.

The standard open operation for ALI secondary to embolism is surgical exploration with Fogarty balloon thromboembolectomy \[15\]. Successful embolectomy occurs when the arterial intima is not damaged and the distal arterial tree was patent prior to embolization. Typically a femoral exploration is performed for suspected aortic, iliac, or femoral thromboemboli while a below the knee popliteal exploration is performed for suspected popliteal or tibial thromboemboli.

If there is significant preexisting atherosclerotic occlusive disease, an endarterectomy with patch angioplasty may be a necessary adjunct to an embolectomy. This is seen commonly with in situ thrombosis of a diseased common femoral artery. When thrombosis of significant arterial segment occurs such that flow cannot be adequately restored by a focal thromboendarterectomy, a surgical bypass is generally necessary. In these instances, definition of a distal target for bypass with preoperative or on-table angiography is exceedingly helpful. The type of bypass is dictated by the clinical scenario. For example, when there is bilateral ALI, an aortic occlusion or saddle emboli is suspected. If bilateral femoral thromboembolectomy does not adequately restore perfusion, an axillofemoral bypass may be undertaken.
Catheter-directed thrombolysis (CDT) for ALI was first introduced in the 1990s [16]. The goal of thrombolytic therapy is to restore flow through the occluded arterial segment and, in doing so, to “uncover” the underlying culprit lesion which can then be definitively addressed via standard open surgical or endovascular methods. The major advantages of using CDT to restore blood flow in the critical care population is the avoidance of a major open surgical operation and the gradual reestablishment of blood flow to the affected extremity avoiding ischemia–reperfusion injury. The most appropriate candidates for thrombolysis are patients with category I or IIa disease, or those with in situ thrombosis. Patients with imminently threatened limbs that may lose neurologic function without immediate revascularization are not appropriate candidates as thrombolysis may take 2 to 3 days to restore blood flow.

The general procedure is as follows:

1. Endovascular access is gained utilizing the Seldinger technique under ultrasound guidance.
2. Angiogram is accomplished to elucidate the location and extent of disease.
3. The occluded arterial segment is traversed with a guidewire.
4. A lysis catheter is placed across the occluded segment.
5. A thrombolytic agent is administered as a bolus and a continuous infusion is started.
6. Serial laboratory testing as well as neurovascular examinations are done.
7. Reimaging is done in 24 hours to ascertain the success of the thrombolysis and angioplasty/stenting can be performed at the conclusion of thrombolytic therapy.

Monitoring of patients undergoing thrombolysis is critical. After the initiation of thrombolysis, patients are returned to the ICU. Serial laboratory studies are performed to reduce the risk of a systemic thrombolytic state which would increase the risk of intracerebral hemorrhage (ICH) or other spontaneous bleeding. During fibrinolysis,
thrombus dissolves and the body recruits coagulation factors to reform the thrombus; therefore coagulation factors and fibrinogen are consumed. Laboratory values monitored include fibrinogen, complete blood count, prothrombin time (PT)/international normalized ratio (INR), PTT. A decrease in fibrinogen by more than 50% or below 100 mg per dL implies an excessive consumption of coagulation factors leading to an increased risk of ICH. Serial PT/INR and PTTs should be assessed to reduce the risk of systemic anticoagulation.

In the United States, the most commonly used drugs are urokinase and recombinant tissue plasminogen activator usually marketed as alteplase. There are two multicenter randomized clinical trials that established the efficacy of CDT [17,18]. It should be noted that thrombolytic therapy is most effective for freshly formed thrombus and that the trials demonstrated poor efficacy for patients who had limb ischemia of the duration greater than 14 days.

Several professional societies have published consensus guidelines on the surgical management of ALI. The CHEST guidelines published in 2012 recommend open surgery as compared to CDT (Level 1B evidence), yet CDT is a recommended modality for appropriate patients [19]. In 2005, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines on Peripheral Artery Disease (PAD) were published in collaboration with cardiologists, vascular surgeons, vascular medicine, and interventional radiology; their conclusion was CDT is effective and indicated for patients with ALI of fewer than 14 days’ duration [20].

There are several adjunctive measures to improve the success of thrombolysis, notably mechanical thrombectomy and aspiration thrombectomy. There are two FDA-approved mechanical thrombectomy devices, the AngioJet and the Trellis Thrombectomy system, which can supplement thrombosis by reducing clot burden and more rapidly restoring perfusion. While CDT is an attractive option for a select patient group, it is contraindicated for patients at high risk of hemorrhagic complications. There are several contraindications to treatment with thrombolytic therapy (Table 54.2). When patients are selected appropriately, approximately 1% of patients will have a life-threatening hemorrhage, most ominously an ICH.

POSTOPERATIVE CARE

Postoperative management of the revascularized acute limb ICU patient focuses on resuscitation and anticoagulation. These patients must be aggressively resuscitated to prevent systemic complications of ischemia–reperfusion injury. Additionally, systemic anticoagulation must be continued as rethrombosis or recurrent embolism occurs among 6% to 46% of patients [21,22].
Ischemia–reperfusion injury may result in limb and multisystem organ dysfunction. As ischemic muscle is reperfused, cellular edema and interstitial fluid shifts may occur. Symptoms include pain, hypoesthesia, and weakness of the involved limb. Rhabdomyolysis may occur; as the muscle groups are reperfused, the ischemic muscle is broken down and by-products are released into the bloodstream—notably myoglobin and potassium. The elevated potassium can lead to cardiac arrhythmias and the myoglobin can cause acute kidney injury. Treatment is mainly supportive, aggressive fluid resuscitation with an isotonic fluid; occasionally, a bicarbonate drip is indicated to alkalinize the urine. In cases of severe hyperkalemia, calcium carbonate may help to stabilize the cardiac myocyte membrane while IV insulin and an ampule of D50W can help to redistribute potassium into cells. Patients can become profoundly acidotic and in rare cases require hemodialysis [23].
COMPARTMENT SYNDROME

Compartment syndrome occurs when the reperfused muscle swells inside fixed factual compartments. When compartment pressures exceed 25 to 30 mm Hg, the extravascular pressure then exceeds capillary pressure and blood flow is restricted leading to tissue infarction. The first signs are pain, numbness, and paresthesias. Of the four compartments to the distal lower extremity, the anterior compartment is the most susceptible to compartment syndrome. Symptoms are focused around deep peroneal nerve injury and include numbness to the first web space and decreased foot dorsiflexion. Management is operative; immediate four-compartment fasciotomies are necessary to prevent any further nerve or muscle damage.
UPPER EXTREMITY ACUTE LIMB ISCHEMIA

Upper extremity ALI is far less commonly encountered than lower extremity ALI and typically results from cardioembolic events. In situ thrombosis is uncommon since atherosclerotic disease is rare in the upper extremities. Emboli typically lodge at the brachial or axillary artery. The clinical presentation can be similar to lower extremity ALI; however, more commonly, patients report decreased sensation and strength without pain. Upper extremity ALI can be diagnosed with history and physical examination alone, although duplex imaging can confirm the diagnosis. CT angiogram of the chest and upper extremities is a useful adjunct for determining the anatomic location of the occlusion and to assist with operative planning [24,25].

First-line treatment for upper extremity ALI is anticoagulation. Most patients report a significant improvement in symptoms with anticoagulation alone. The upper extremities have robust collateral circulation compared to the lower extremities, so the risk for tissue loss is lower. However, patients who develop upper extremity ALI are at risk of developing chronic arm claudication or even severe neuromuscular dysfunction with incidence rates of 50%. Therefore, patients who are medically able to tolerate surgery or at risk of loss of upper extremity function should undergo revascularization [26].

Surgical treatment of upper extremity ALI is generally performed through a brachial artery exploration and Fogarty balloon thromboembolectomy. The procedure can be performed under local or regional anesthesia with sedation if the patient is unable to tolerate general anesthesia. Postoperatively, the patient should remain anticoagulated and undergo serial neurovascular examinations. Upper extremity compartment syndrome is less common, so prophylactic fasciotomies are rarely performed. However, careful neurologic monitoring is indicated to identify a developing compartment syndrome. In addition, a full workup including cardiac echocardiogram and CT angiography of the chest should be performed to determine the etiology of the ALI event. Patency rates for upper extremity revascularizations are high and amputation rates are negligible. However, studies have shown overall mortality rates of patients with upper extremity ALI to be as high as 50% over 5 years due to the incidence of multiple medical comorbidities in the population.
In general, recommendations are as follows:

1. Systemic anticoagulation is a mainstay in the management of ALI in all patients to minimize propagation of thrombosis and prevent recurrent events after revascularization.

2. Immediate surgical revascularization is indicated for patients with an immediate threatened limb, Rutherford classification IIb, to avoid an unacceptable delay in reperfusion.

3. In patients with a marginally threatened limb, CDT is an appropriate treatment modality.

4. Primary amputation is indicated for patients with an irreversibly ischemic limb.

5. In hemodynamically unstable patients or those with severe multisystem dysfunction, the mortality risk of revascularization may be prohibitive. In these patients, conservative medical management with a “life over limb” approach may be appropriate.

Surgeons play an essential role in providing optimal palliative care for patients and families. Palliative surgery is best defined as the deliberate use of a procedure in the setting of incurable disease for the intention of relieving symptoms, minimizing patient distress and improving quality of life [1]. Because the goal of the surgery is not curative but rather the alleviation of suffering, the decision to proceed requires not only technical judgment, but also a sincere understanding of the patient’s symptoms, the clinical, emotional, psychological, and social situation and the goals of care of both the patient and family. Typically, surgical outcomes are measured in terms of morbidity and mortality. However, given the stated goals of palliative surgery, morbidity and mortality are not necessarily the most effective measures of success. Rather outcomes such as the presence and duration of patient-acknowledged symptom relief may be much more salient [2,3]. Treatment plans which effectively achieve these goals must balance the potential benefit of durable symptom relief with the risk of treatment toxicity, while considering the patient’s medical condition, performance status, prognosis and life expectancy, other medical treatment options and cost-effectiveness. The complex decisions required to manage these patients can challenge even the most experienced surgeons.

For patients with an incurable disease who are in the intensive care unit (ICU), the role of surgery in the management of their care may be even less clear than for patients whose clinical condition does not require intensive care. This lack of clarity is often multifactorial and includes a potentially more limited survival time, the patient’s ability to undergo anesthesia safely, the magnitude of the surgery required to address the problem, whether or not the surgical problem is the cause or effect of the patient’s critical condition, the likelihood of success of the surgery, the risk of complications, the availability of other treatment options, and the
overall goals and wishes of the patient and family. Furthermore, the fact that most surgical procedures tend to inflict some pain initially adds an additional element of complexity to this equation. This chapter reviews the current status of, and evolving approach to, palliative surgery, as well as the management of some of the more common indications for palliative surgery consults in the ICU. It will also address ways to improve communication and decrease moral distress among surgeons related to interactions with patients and families in the end of life setting.

CURRENT STATUS OF PALLIATIVE SURGERY

The greatest experience with palliative surgery revolves largely around its use in patients with advanced malignancies. Palliative surgical consultations have been reported to represent up to 40% of all inpatient surgical consultations at major cancer centers [4]. In fact, studies from two stand-alone cancer centers, the Memorial Sloan Kettering Cancer Center (MSKCC) in New York, New York, and the City of Hope Cancer Center in Duarte, California, showed that 6% and 12.5% of all surgical procedures were performed for palliation, respectively [5,6]. In the largest study ever looking at outcomes for palliative surgery from the MSKCC, Miner et al. [6] reported on the results of 1,022 palliative surgeries performed over the course of 1 year from July 2002 to June 2003. During that time, palliative interventions exceeded the combined number of esophagogastrectomies, gastrectomies, pancreatectomies, and hepatectomies performed. The most common indications for palliative surgery consults included gastrointestinal obstruction (34%), neurological symptoms (23%), pain (12%), dyspnea (9%), and jaundice (7%). Symptom improvement or resolution was achieved in 80% of patients by 30 days with a median duration of symptom control of 135 days. The primary symptom recurred in 25% of patients and treatment of additional symptoms was required in 29%. The 30-day morbidity and mortality associated with the palliative procedures was 29% and 11%, respectively. Not unexpectedly, postoperative complications had a negative impact and reduced the likelihood of symptom improvement to 17%. Median survival from the time of the palliative procedure was 194 days. The authors concluded that there is an opportunity for a significant number of patients to achieve durable improvement in quality of life given the median symptom-free survival of 135 days and a median survival of 194 days. Others have shown similar findings including an improved overall survival associated with symptom improvement in one study [1,6–8] (Table 55.1).

<sup>a</sup>Grade 3/4 major surgical morbidity only.

NR, not reported; QOL, quality of life
Because the primary goal of palliative surgery is to improve quality of life or relieve symptoms, it has been argued that traditional surgical outcome measures such as morbidity, mortality, disease recurrence, and survival are not sufficient to determine the success or failure of a palliative intervention. While understanding the risks (morbidity and mortality) of a procedure is important, it is equally important to assess the potential benefits. Because the impact of different specific palliative interventions can vary significantly—i.e., the impact of an indwelling catheter for a refractory pleural effusion may be significantly greater than that of a venting gastrostomy—it is difficult to quantify and compare the benefit of different procedures. One approach to addressing this issue is the use of patient-reported outcomes [2]. Patient-reported outcomes are surveys used to assess a patient’s well-being from the patient’s perspective. These surveys often include health-related quality of life or symptom assessment and are appropriate for assessing a surgical intervention intended to improve quality of life or relieve symptoms. However, currently, there are no validated quality of life instruments solely focused on palliative surgical outcomes, making it difficult to identify patients who benefit from these interventions, and the use of patient-reported outcomes in palliative surgery is limited [1,9]. One prospective pilot study using standardized, validated instruments demonstrated the challenges of interpreting outcomes after palliative interventions due to the continued loss of global health status during the end of life [1]. In a second study, the authors found that the death rate of 40% prior to study completion at 90 days post-procedure had a significant impact on the questionnaire response, clearly demonstrating the challenge of measuring the success of interventions in actively dying patients [10]. However, validating these interventions is essential given the high proportion of interventions that are palliative and the relatively high mortality rate which can significantly impact the overall operative mortality of an institution. In this age of quality-based reimbursement, this impact cannot be ignored and a means of incorporating palliative intent as a specific data element for comparing surgical outcomes needs to be devised.

As with any treatment—surgical or medical—another opportunity for improving the outcomes of palliative surgery is through optimal patient selection. The end of life setting presents a unique set of circumstances requiring difficult decisions with limited data. Using an open-ended questionnaire, Collins et al. [11] investigated the patient reasoning behind treatment choices after palliative surgical consultation. Of 98 patient enrolled in this prospective study, 54 were treated nonoperatively and 44 were treated with surgery. Symptom relief and/or quality of life was the reason for the treatment choice in only 46% of patients, and 40% said that they made their choice based on the doctor’s recommendation.
Twenty percent opted for care in hopes of prolonging their lives. This study demonstrates the powerful influence of the physician in the decision-making of patients at this stage of life, and the need for clear communication about goals and expectations between all parties.

Another critical party in these decisions is the patient’s family. To help surgeons navigate this intriguing and often challenging dynamic, Miner et al. [1] have previously proposed and studied the use of the “palliative triangle” as an approach to improving patient selection and patient-acknowledged outcomes for palliative surgery (Fig. 55.1). Through the dynamics of the triangle, the patient’s complaints, values, and emotional support are taken into account while weighing the medical and surgical alternatives. In addition, the triangle offers an opportunity to learn about and address a patient’s and/or family’s expectations regarding the intent of the proposed procedure helping to moderate any incongruent expectations between surgeon, patient, and family members. Miner et al. [12] prospectively investigated the use of the palliative triangle technique during palliative surgery consultation in 227 patients with symptomatic, advanced, incurable cancer. This is one of the few studies that included both patients who did and did not undergo a palliative procedure. More than half (53.3%) of the patients did not undergo a procedure. Reasons cited included low symptom severity, decision for nonoperative palliation, patient preference, and concerns about complications. Of the patients who did undergo a palliative procedure, 90.7% reported symptom resolution or improvement. The morbidity and mortality associated with these procedures was 20.1% and 3.9%, respectively. The median survival was 212 days. The authors concluded that use of the palliative triangle can help improve patient selection which is associated with significantly better symptom resolution and few postoperative complications compared with previously published results. The authors have also postulated that building this strong relationship may explain the observation of high patient satisfaction toward surgeons after palliative operation—even if there is no demonstrable benefit [1].
FIGURE 55.1 The palliative triangle. The palliative triangle facilitates interactions between patients, families, and surgeons, and helps guide patients to the best decisions regarding palliative surgery.

MANAGEMENT OF COMMON PALLIATIVE SURGERY CONSULTATIONS

This section reviews management options for some common palliative surgery consults in ICU patients. While this list is not comprehensive, it does offer a framework for approaching any palliative surgery situation. Management of other specific surgical problems encountered in the ICU is discussed elsewhere in the text. When surgery is not an option, it is important to know how to palliate common symptoms in patients with advanced illness (see Chapter 35).

Bowel Obstructions

One of the most common palliative surgical consults is for bowel obstruction. Bowel obstructions can occur at any level of the gastrointestinal tract from the stomach to the rectum. Depending upon the etiology (adhesions, cancer, stricture), the management can vary from nonoperative nasogastric decompression and bowel rest to bowel resection and/or intestinal diversion. In the setting of advanced illness such as cancer, and for patients who are in the ICU, management can be complicated and multimodal. Regardless of the etiology, initial management of a patient with a bowel obstruction should include appropriate intravenous fluid resuscitation based upon the degree of dehydration and the site of the obstruction and correction of any metabolic abnormalities. The bowel should be decompressed with a nasogastric tube if the patient is vomiting, and the patient should not be allowed to eat or drink to decrease gastrointestinal stimulation and secretions. Serial abdominal examinations for signs or symptoms of peritonitis are essential. Imaging studies, such as an abdominal series and/or a computed tomography scan of the abdomen and pelvis, are helpful to determine the level and nature of the obstruction. They can also demonstrate the presence of extraluminal air suggesting a perforation, and the presence or absence of ascites.

Patients who are hemodynamically stable, who do not have peritonitis and have a normal or only mildly elevated white blood count (especially in the setting of dehydration), can initially be monitored closely (with the measures mentioned above) and given a chance for the obstruction to resolve without surgery. Signs and symptoms of peritonitis or an imaging study suggesting a “closed loop” obstruction (a loop of intestine twisted around its mesentery) are indications for a more urgent surgical intervention. Often the exact nature of that intervention cannot be
determined until the time of surgery—adding an additional element of cognitive and emotional uncertainty that must be borne by the patient, family, and surgeon. Surgery may include resecting the section of obstructed intestine if it appears to be an isolated site, performing an intestinal bypass if the site cannot be resected, performing a diverting ostomy (either small or large bowel depending on the location of the obstruction), or placing a decompression gastrostomy tube for venting the stomach if the obstruction cannot otherwise be relieved. In the setting of a malignancy, these operations can be challenging, both technically as well as with regard to the decision-making, and they pose a high risk for perioperative morbidity and mortality [13].

If the obstruction is located in the rectum or rectosigmoid colon or duodenum, it is reasonable to consider an endoscopic stent placement rather than surgery as the initial intervention. While the presence of carcinomatosis has been shown to increase the risk of failure of endoscopic stent placement for colonic obstruction, there is a 77% to 85% success rate [14–17]. For patients with a limited prognosis, an opportunity to avoid an operation that could involve either an intestinal diversion and ostomy or venting gastrostomy tube is an important consideration. For patients in whom it is felt that surgical or endoscopic relief of the bowel obstruction is not feasible, it is reasonable to evaluate them for a percutaneous endoscopic gastrostomy tube placement for gastric drainage.

Surgical decision-making becomes more challenging for end of life patients who are not stable and require a decision regarding an emergent operation. It may be argued that this is not a purely palliative surgery consult as the surgical intervention has the potential to rescue the patient from a life-threatening complication of their life-limiting illness. On the other hand, it may also be considered palliative as it will not cure the patient of the underlying disease process. Needless to say, this is often an emotionally charged time, even for patients with long-standing illness such as advanced cancer, because they are now faced with the imminent risk of dying. A recent study by Cauley et al. [18] reported the results of a retrospective cohort study of 875 disseminated cancer patients undergoing emergency surgery for obstruction (n = 376) or perforation (n = 499). Of the 376 patients who underwent emergency surgery for obstruction, the 30-day mortality rate was 18% with a 41% morbidity rate and 60% were discharged to an institution. Dependent functional status and ascites were independent preoperative predictors of death at 30 days. Postoperative predictors of mortality included respiratory and cardiac complications. Only 4% of patients had “do not resuscitate” orders in place prior to surgery. Further underscoring the dismal prognosis in this particular situation, a study by Pameijer et al. [19] showed that patients with metastatic cancer who presented with obstructive symptoms had a
median survival of 3 months regardless of operative or no-operative management.

While most patients will survive the initial operation, a substantial number will die soon after the surgery and many experience postoperative complications, reoperations, stays in nursing homes, or hospital readmissions. Such events clearly impact the patient’s quality of life. While these data are helpful for surgeons and caregivers to advise patients of the risks of surgery, set expectations for the postoperative experience, discharge location and overall survival, both at the time when the decisions is made for surgery and if complications occur, important data regarding whether the goals of the patients and families were met and whether or not they would make the same choice again are still severely lacking at this time.

Gastric Outlet and Duodenal Obstruction

Obstruction of the gastric outlet and/or duodenum is another common indication for palliative surgical consultation. Most patients present with nausea and vomiting of undigested food. Physical examination usually demonstrates upper abdominal distension and tympani. Imaging studies often reveal a distended stomach with retained enteric contents. As with a lower intestinal obstruction, acute symptoms should be initially managed with nasogastric decompression, bowel rest, and intravenous resuscitation, including aggressive electrolyte repletion. (For patients with chronic gastric outlet obstruction, special attention should be paid to chloride replacement which is lost in large quantities with emesis of gastric secretions.) If significant weight loss is present or if there may be a delay in definitive treatment, it may be reasonable to consider parenteral nutrition while planning additional palliative measures.

Options for managing upper gastrointestinal obstructions include intraluminal stenting, surgical bypass, and decompression gastrostomy with possible feeding jejunostomy. Similar to colonic stenting, the potential benefits of duodenal stenting include immediate palliation of nausea and vomiting with a less invasive procedure than surgical bypass and earlier return to oral nutrition [20,21]. (Restoring a person’s ability to eat and drink is one of the most rewarding palliative interventions.) Stents may be particularly useful for patients with advanced malignancy, who are at increased risk of surgical complication or who are technically inoperable. Flexible self-expanding metal stents can be placed using endoscopic or fluoroscopic techniques. Stenting has been shown to provide a comparable survival outcome and equivalent morbidity and
mortality to surgical bypass [22]. In a systematic review of the literature from 1990 to 2008 comparing endoscopic stenting with open surgical bypass, Ly et al. [22] found that endoscopic stenting was more likely to result in tolerance of oral intake (OR 2.6; p = 0.002) in a shorter period of time (mean difference of 6.9 days, p < 0.001) with a shorter hospital stay (mean difference 11.8 days, p < 0.001) as compared with open surgical bypass. Similar findings were reported by Zheng et al. [23] Based upon these findings, it is also likely that stenting is less expensive than surgical bypass. The major limiting factor for the endoscopic approach is being unable to pass the scope through the obstruction. The major complications reported are gastric ulceration, bowel perforation, biliary obstruction, stent dysfunction, and stent migration. Stent placement would be contraindicated in patients with multiple levels of intestinal obstruction and should be considered carefully for patients with peritoneal carcinomatosis who are at risk of more distal obstructions.

For patients in whom stenting is not an option, surgical bypass can relieve both the symptoms of the obstruction and allow the patient to resume enteral nutrition. Surgical bypass, most commonly in the form of a gastrojejunostomy, can either be performed laparoscopically or through a relatively small upper midline incision. The estimated risk of morbidity and mortality from these procedures is 25% to 60% and 0% to 25%, respectively [22,23]. While surgical bypass is usually technically successful, patient selection with regard to preoperative nutritional status and life expectancy is imperative to the palliative success of this approach. For example, in addition to general surgical risks such as bleeding or infection, a patient with chronic gastric outlet or duodenal obstruction who is malnourished is at increased risk of a leak from the intestinal anastomosis. Other potential complications specific to gastric bypass include dumping syndrome, alkaline reflux gastritis, and delayed gastric emptying.

Placement of a gastrostomy tube for decompression is another option for palliation of gastric outlet, duodenal and nonoperable small bowel obstruction or profound gastrointestinal dysmotility from carcinomatosis. Gastrostomy tubes can be placed either endoscopically, fluoroscopically, or surgically (either laparoscopic or open). Decompression gastrostomy tubes provide patients the ability to drain the stomach as for nausea and to avoid vomiting. It also allows them to drink liquids and eat some soft foods for pleasure and comfort. It does not allow for the enteric maintenance of nutrition. Many endoscopists, surgeons, and interventional radiologists are leery of placing gastrostomy tubes in the setting of malignant ascites. They are concerned about the risk of infecting the ascites, intraperitoneal leakage from the stomach due to poor apposition to the anterior abdominal wall, as well as leakage of ascites from around the tube. There is a growing body of literature
demonstrating the safety of placing gastrostomy tubes in patients with malignant ascites from a variety of tumors [24–26]. Paracentesis prior to or concurrent with gastrostomy placement is advisable. Also, consideration of placing a peritoneal drainage catheter at the time of gastrostomy may also help lower any risk associated with the ascites. As gastrostomy may be the only viable palliative option for these patients, all efforts to manage the ascites and increase the safety of gastrostomy placement are warranted.

**Ascites and Pleural Effusions**

Two other common palliative surgical consultations for the ICU patient are for management of peritoneal ascites and pleural effusions. Unfortunately, while the symptom relief from a paracentesis or thoracentesis is immediately helpful, it is usually temporary. For patients requiring frequent drainage of either the peritoneal or pleural cavity, a tunneled intraperitoneal catheter that can be intermittently connected to a self-contained vacuum drainage system is a helpful option [27]. These catheters can be placed under local anesthesia either by interventional radiology or surgery. Another option for the treatment of malignant ascites is hyperthermic intraperitoneal chemotherapy (HIPEC). A number of studies have demonstrated the efficacy of HIPEC in the treatment of malignant ascites [28,29]. As there is often no cytoreductive surgery involved, this can be done laparoscopically, which, although less invasive, still does require general anesthesia. This option may be less appropriate for patients who are in the ICU and should typically be reserved for patients with a longer life expectancy and higher performance status.

Similarly, an alternative treatment option for patients with recurrent malignant pleural effusion is pleurodesis. Pleurodesis can be performed using a number of different agents including talc, chemotherapy, or abrasion. The intent is to create an inflammatory reaction within the pleural cavity resulting in fusion of the visceral and parietal pleura, thereby obliterating the peritoneal space and the opportunity for fluid re-accumulation. Talc has been shown to be the most effective pleurodesis agent in randomized clinical trials with reported success rates of 60% to 90% [30]. However, although these procedures can be done at the bedside, they do require the placement of a larger bore chest tube and can be rather painful [31].

**Intestinal Perforation**

Intestinal perforation due to a complication of a life-limiting illness can be one of the most challenging consults at the end of life in the ICU setting. Unlike patients with a bowel obstruction, patients with a
perforated viscus are more likely to have pain from peritonitis, adding another element of consideration to both the decision-making process and the emotional charge of the situation. Currently, there is a small, but growing body of literature supporting the use of nonsurgical management for bowel perforation in select (hemodynamically stable, non-peritonitic) patients. Some studies have reported a greater than 90% success rate in nonsurgical management of patients with perforated diverticulitis [32]. Unfortunately, for patients with advanced cancer, who are not stable or who have peritonitis, and who undergo emergent surgery, the outcomes are even worse than for those with a bowel obstruction. In the study by Cauley et al. [18], among the 499 patients who underwent surgery for perforation, the 30-day mortality was 34% with a morbidity rate of 67%, and 52% of patients were discharged to an institution. Independent preoperative predictors of death at 30 days included renal failure, septic shock, ascites, dyspnea at rest, and dependent functional status. Postoperative respiratory complications and advanced age (greater than 75 years) were also predictors of mortality. Similar to the patients who presented with a bowel obstruction, only 4% had a “do not resuscitate” order in place prior to surgery despite the advanced nature of their cancer. Again, while data from studies like this may help surgeons answer questions about the risks associated with surgical interventions and guide some patients in their decisions, in a society in which people are not prepared for dying, these data can often make things harder for the surgeon who is asked to operate in the face of such overwhelming odds.

Avoiding Moral Distress

Caught between patients who are suddenly facing their own mortality and families who are not ready to let go, the smallest amount of hope that surgery offers makes even the most daunting risks seem worth taking. This is a setting in which surgeons, and other affiliated providers, experience moral distress. Professionalism demands that the surgeon make a sincere effort to understand and be understanding of the perspective of the patient and family—without realistic expectation of the same in return. This can be particularly challenging when the surgeon is busy or when these events occur in the middle of the night. In the name of “full disclosure and informed consent,” some surgeons paint as bleak a picture as possible for the patient and family, in an effort to dissuade the patient from choosing surgery. When, despite these efforts, the patient and family ask for surgery, some surgeons expect a tacit agreement that the patient will endure to the end, including any additional procedures or
maneuvers that may be required—surgery, feeding tubes, tracheotomy, dialysis, rehabilitation, etc. There is often a sense of frustration and betrayal on the part of the surgeon when within a few days after the index surgery, the family decides to stop any further life-prolonging care. It is for this reason that understanding the perspective of the patient and family is critical to both outcome of the encounter and the surgeon’s well-being (see Chapter 36).

It is for challenging situations like this that the palliative triangle can be most helpful. As described above, use of the palliative triangle can help create a space in which all three parties are given a chance to express their concerns and be heard. It is also significant in that it helps the surgeon separate the patient’s goals and understanding from that of the family’s and vice versa. It also gives the surgeon’s goals and understanding equal weight in the decision-making. However, success of the palliative triangle approach is predicated on the surgeon’s mind-set. If the surgeon truly hopes to influence the behavior of the patient and the family in an efficient and professional manner, an outward mind-set, in which the patient’s and family’s objectives matter like the surgeon’s objectives matter, is essential. The Arbinger Influence Pyramid is a proven leadership approach to influencing behavior which is readily applicable to patient–family–physician interactions [33] (Fig. 55.2). Starting at the base of the pyramid, the surgeon must adjust his or her mind-set to an outward mind-set in which the goals and objectives of the patient and family matter equally with his or hers. The outward mind-set will then facilitate building a relationship with the patient and those who have influence on the patient—namely the family. Building this relationship can happen simply through introductions and a sincere expression of empathy for the challenging situation which the patient and family are facing. Next, the surgeon needs to listen and learn what the patient and family know about the situation and what their hopes, goals, and objectives are. Afterward, the surgeon can teach the patient and family what they need to know, correct any misconceptions, answer questions, review the risks, benefits, and indications for surgery and the alternative options, and make an engaged recommendation based upon the goals of all three parties. From there, the surgeon, patient, and family can usually come to a mutually agreed upon goal and care plan (see “structured family meetings” in Chapter 34). There are a few key points about using the Influence Pyramid. First, time and effort spent at the lower levels of the pyramid is what ensures effectiveness at the higher levels. Second, the solution to a problem at one level of the pyramid will be found in spending more time at a lower level of the pyramid. Third, the effectiveness at each level of the pyramid depends on the effectiveness of the level below and ultimately on the deepest level of the pyramid—the mind-set.
FIGURE 55.2 The Arbinger Influence Pyramid. The Influence Pyramid is a proven framework designed to help influence behavior and improve results beginning with a shift in mind-set.

BENEFITS OF EARLY PALLIATIVE CARE CONSULTS

Initiation of a palliative surgery consultation is an appropriate time for initiating a palliative care consultation as well, if one has not already been obtained. While some physicians and patients view a palliative care consult as “giving up,” this could not be further from the truth. Unlike hospice (which is a medical insurance benefit that requires a life expectancy of less than 6 months if the life-threatening disease is untreated and the patient forgoes disease-directed treatment), all patients with symptoms from an illness or its treatment benefit from palliative care. While most patients’ symptoms can be adequately palliated by their primary physician (either their primary care provider or primary specialist), advanced, life-threatening illnesses, such as cancer, can pose additional challenges in terms of physical, emotional, psychological, spiritual, and social symptomatology. It is preferable to initiate a palliative care consultation before these symptoms become unmanageable, as this will make it seem less like “giving up” when there is an acute need for the expertise of a palliative care provider.

One way to overcome the inertia of referring patients to palliative care early is to normalize it. Many institutions have made it part of their cancer center’s protocols to refer all patients with advanced cancer to palliative care from the initial cancer center visit. This allows the palliative care team to tell patients and their families that all patients with advanced cancer are seen by palliative care and that it is simply part of the multidisciplinary team effort to care for the patient and family. Similar efforts can also be made in the ICU for selected patients (see Chapter 33). Palliative care consultation can help take some of the burden off the primary specialist for conducting the harder conversations around goals of care and advanced directives and allowing them to focus on the plan of treatment. Having these difficult conversations early is essential for the comprehensive management of life-threatening illness and should not be avoided due to provider unease.

Earlier palliative care involvement can also help with the transition to hospice when appropriate. Recognition of that time may come first to the primary specialist when further illness-directed treatment is likely to do more harm than good to the patient and family when they decide that the
burden of treatment is not worth the limited potential for more time. Unfortunately, it is not infrequent that both parties do not arrive at this recognition at the same time. The treating physician may find it easier to continue to treat the patient who insists on continuing to “fight” even knowing that “fighting” may take time away from the patient. Similarly, the patient may find it easier to keep doing treatment rather than “disappoint” the treating physician by stopping. With an early palliative care intervention, conversations about hospice as a potential option can be started early leaving plenty of time to correct any misconceptions. Patients and families can learn that the mission of hospice is neither to prolong life nor hasten death but to provide comfort and dignity and optimize the quality of life that is left. It can help dispel other concerns such as losing contact with the primary care provider, not being allowed to go to the hospital if necessary, not being allowed to come off hospice if a new treatment becomes available, etc. They will also learn that hospice provides support to both the patient and the family through an interdisciplinary team of providers including physicians, nurses, social workers, chaplains, and volunteers. Hospice also helps families prepare for their loss and provides bereavement programs after the death. It has also been shown that patients who understand their poorer prognosis near the end of life are unlikely to choose invasive treatments that can prolong suffering and time away from home [34–36]. A palliative care consultant who is an expert in communication can be a huge help with this aspect of the patient’s care (see Chapter 34).
CONCLUSIONS

Surgery and surgeons are an essential component of comprehensive palliative care. Surgical decision-making for palliation in the end of life setting is complex and challenging. These situations often demand the highest level of surgical judgment. In addition to consideration of the risks in terms of the traditional surgical outcomes measures such as morbidity and mortality, decisions must also include end points such as the probability and duration of symptom resolution, the impact on overall quality of life, pain control, and cost-effectiveness. Regardless of the indication for a palliative surgery consultation, deliberations over surgical palliation must consider the clinical condition and performance status of the patient, the prognosis of the disease process, the availability and success of nonoperative management, and the individual patient’s quality of life, life expectancy, and goals of care. Clinicians must remain flexible to meet the ever-changing needs of the patient and family. Use of a tool such as the palliative care triangle and the Influence Pyramid can facilitate the difficult conversations that often accompany these consults and help guide the patient, family, and surgeon to make the optimal choice for the patient. Early palliative care consultation has also been shown to improve outcomes in terms of quality of life, overall survival and cost-effectiveness, as well as mitigating some of the moral distress that can arise in these emotionally charged situations.

TRANSPLANTATION
STEPHANIE M. LEVINE
In 2016, over 13,000 patients on the national organ transplant waiting list in the United States died or were delisted because they had become too ill before a suitable donor organ became available [1]. Almost assuredly, this number underestimates the actual magnitude of the problem. Many patients with end-stage organ failure are currently not even considered for transplantation (and consequently are not listed) because of the strict recipient selection criteria that are being applied—in part as a result of the severe, ongoing organ shortage. The widening gap between available deceased donor organs and the number of patients waiting is a result of the explosive, increased use of organ transplantation therapy over the past 40 years (Tables 56.1 and 56.2), with which the deceased donor pool has not kept pace (Fig. 56.1) [1,2].

(Data from references [1–4,9])
The single most important factor that has been identified in this equation is the failure to maximize the conversion of potential deceased donors to actual donors, primarily because of the inability to obtain consent for organ recovery. The rates of consent granted by families of potential deceased donors range only from 0% to 75% and appear to vary widely among geographic regions and ethnic groups \([10–12]\). Lack of dissemination and poor presentation of information to the public, misperceptions in the general population regarding the beneficial nature of organ transplantation, and the necessity of organ recovery from deceased donors, as well as inappropriate coordination of the approach to families of potential donors contribute to the stagnation of the organ supply \([11–13]\).

The role of physicians who care for critically ill patients in altering this current situation is crucial \([14]\). It is their responsibility to minimize deceleration of the critical care provided to patients that have suffered a catastrophic brain injury, to identify potential donors, to seek their early referral to an organ procurement organization (OPO), and to ensure that families are adequately approached. This will maximize families’ opportunities to donate a family member’s organs and allow the families to experience the beneficial effects of donation for the bereavement process (Table 56.3) \([15]\).

It is estimated that in the United States alone, approximately 250,000 additional life years could be saved annually if consent rates for potential deceased donors could be increased to 100% [16]. Intensive care and emergency medicine physicians are obligated ethically and morally to provide the best possible outcome for a very ill patient. However, after a potential donor has been identified, they are also obligated to seek the best possible outcome for patients with end-stage failure of a vital organ waiting for a transplant by attempting to ensure that organ donation occurs. It is becoming increasingly evident that implementation of critical pathways and standardized donor management protocols play an important role in this context [17–25].

DONOR CLASSIFICATION BASED ON THE CRITERIA USED FOR DETERMINATION OF DEATH
Brain-Dead Deceased Donors

Death is determined based on neurologic criteria. Donation after brain death is the most common type of organ donation (currently over 80% of all donors belong in this category) [2]. In most Western developed countries, brain death is legally equated with death. The diagnosis of brain death rests on the irreversibility of the neurologic insult and the absence of clinical evidence of cerebral and brain stem function. The details of the clinical examination that is required to unequivocally establish brain death are described in this chapter. Organ procurement proceeds only after brain death has been diagnosed and death has been declared.

Donation After Circulatory Death Donors (Formerly Known as Donation After Cardiac Death or Non–Heart-Beating Donors)

Death is determined based on circulatory and respiratory criteria. Further increases of the number of donors in this category are to be expected (Fig. 56.1) [1,2,24,26,27]. Most commonly, families of unconscious patients with severe irreversible traumatic or cerebrovascular brain injury, who do not fulfill the formal criteria of brain death, decide to forgo any further care and wish to donate the organs of their family member. Under this scenario, time and place of death are controlled. Circulatory and respiratory support technologies are discontinued in the critical care unit or the operating room and organ recovery is initiated once death has been pronounced by a physician not belonging to the organ recovery and transplant team [26].

An alternative, by far less common donation after circulatory death (DCD) scenario—uncontrolled death—involves a patient who expires, for example, in the emergency room following massive trauma or a sudden cardiovascular event. In the interest of minimizing warm ischemia time, flushing cannulas may be inserted and possibly even perfusion of internal organs with cold preservation solution might already be started while consent to proceed with organ donation is obtained from the patient’s family. The discussion that surrounds this category of DCD donors includes concerns centered on when to stop the resuscitation effort and whether it is appropriate to perform a procedure (i.e., insertion of flushing cannulas) that presumes consent before actually obtaining it from the family. In light of the severe organ donor shortage, there is renewed public debate about more systematically considering uncontrolled DCD at a larger scale [28].

Other considerations that pertain to both controlled and uncontrolled
DCD donors include: uncertainty regarding the exact definition of death after discontinuing circulatory and respiratory support (there is no standardized definition of, e.g., the minimal duration of asystole after the patient expires following withdrawal of support before death can be pronounced; this is currently subject to considerable interinstitutional variation), and the possibility of the patient at least temporarily surviving the withdrawal of support technologies (backup plans must be clearly defined by each individual institutional DCD donor protocol). Nevertheless, these considerations must be balanced with the right of self-determination based on an individual’s previously documented preferences and the final wishes of a competent patient family. Further debate by the medical community and general public is crucial to address these complex ethical issues and to maximize acceptance of organ donation [28,29]. Without such thorough consideration, the deceased donor concept and the donation system that is currently in place might be harmed or discredited.
CURRENT STATUS OF SOLID ORGAN TRANSPLANTATION

The increased number of solid organ transplant procedures performed during the last 40 years has been paralleled by significant improvements in outcomes including rates of patient and graft survival (Table 56.2). This phenomenon has been attributed to a variety of factors that include (a) the introduction in the early 1980s of the powerful immunosuppressive agent cyclosporin A, followed a decade later by tacrolimus, mycophenolate mofetil, and other new immunosuppressants; (b) the availability of antilymphocyte antibody preparations to prevent and treat rejection episodes (e.g., antilymphocyte and antithymocyte globulin); (c) improvements in organ preservation (e.g., use of University of Wisconsin solution, ex vivo machine perfusion of donor organs); (d) thorough preoperative transplant candidate screening for the presence of comorbid disease processes; and (e) increasing sophistication in the postoperative intensive care of regular and high-risk recipients. In addition, the availability of potent, yet nontoxic, antibacterial, antifungal, and antiviral agents has allowed opportunistic infections in immunocompromised transplant patients to be treated more effectively. In combination with refinement of surgical techniques, these factors have led to increasing success of solid organ replacement therapy.

Thus, transplantation has become the treatment of choice for many patients with end-stage failure of the kidneys, liver, endocrine pancreas, heart, lungs, and small bowel. Successful hand, arm, larynx, and face transplants from deceased donors have also been reported [30–33]. Currently, the only patients who are excluded from undergoing transplantation are those with malignancies (metastatic or at high risk for recurrence) and uncontrolled infections, those who are unable to withstand transplant surgery, or those who have a significantly shortened life expectancy due to disease processes unrelated to their target organ dysfunction or failure.

Kidney

Currently, patients undergoing kidney transplants from deceased donors exhibit excellent graft survival rates (Table 56.2). Renal transplantation dramatically improves life expectancy and quality of life, decreases cardiovascular morbidity and mortality, and rehabilitates the recipients from a social perspective. Kidney transplants are also less expensive from a socioeconomic standpoint than is chronic hemodialysis. For pediatric
patients with chronic renal failure, a functioning renal allograft is the only way to preserve normal growth and ensure adequate central nervous, mental, and motor development.

**Liver**

Patients with end-stage liver failure die unless they receive a transplant. Liver transplants are an effective treatment for many patients, pediatric and adult, regardless of the cause of liver failure: congenital (i.e., structural or metabolic defects), acquired (i.e., due to infection, trauma, or toxins), or idiopathic (e.g., cryptogenic cirrhosis, autoimmune hepatitis). A dramatic improvement in graft survival occurred after the introduction of cyclosporin A (Table 56.2). Currently, there are no reliable means to substitute, even temporarily, for a failing liver other than with a transplantation. Extracorporeal perfusion, using either animal livers or bioartificial liver devices (e.g., hepatocytes suspended in bioreactors), may someday bridge the gap between complete liver failure and liver transplantation, but these therapeutic modalities are still investigational and are far from becoming standard clinical tools. Hepatocyte and stem cell transplants to treat fulminant liver failure and to correct congenital enzyme deficiencies are being studied but are presently not a clinical reality.

**Intestine**

Small bowel transplants are performed in patients with congenital or acquired short gut, especially if liver dysfunction occurs because of long-term administration of total parenteral nutrition and when difficulty in establishing or maintaining central venous access is limiting. If liver disease is advanced, a combined liver–small bowel or, in highly selected cases, a multivisceral transplant (liver, stomach, small bowel, with or without pancreas) can be performed [34].

**Pancreas and Islet**

Primary prevention of type 1 insulin-dependent diabetes mellitus is not possible, but transplantation of the entire pancreas or isolated pancreatic islets can correct the endocrine insufficiency once it occurs. Glucose sensor systems that continuously monitor blood sugar levels coupled with real-time command of an insulin delivery system (implantable pump) and bioartificial and hybrid biomechanical insulin-secreting devices are not yet universally available for routine clinical use. The only effective current option to consistently restore continuous near-physiologic normoglycemia, however, is a pancreas transplant [35–37]. Good metabolic glycemic control decreases the incidence and severity of
secondary diabetic complications (neuropathy, retinopathy, gastropathy and enteropathy, and nephropathy). Most pancreas transplants are performed simultaneously with a kidney transplant in preuremic patients with significant renal dysfunction or in uremic patients with end-stage diabetic nephropathy. Selected nonuremic patients with brittle type 1 diabetes mellitus (with progression of the autonomic neuropathy or recurrent severe hypoglycemic episodes, and with repetitive episodes of diabetic ketoacidosis) can benefit from a solitary pancreas transplant (without a concomitant kidney transplant) to improve their quality of life and to prevent the manifestation and progression of secondary diabetic complications. Evidence suggests that a successful pancreas transplant can achieve these goals in uremic and in nonuremic recipients and decrease mortality [35]. Islet transplants are undergoing intensive clinical investigation. Results of transplanting allosislets from deceased donors are encouraging in the short term [36]; however, long-term results are less favorable [37].

Heart

Heart transplantation is the treatment of choice for patients with end-stage congenital and acquired parenchymal and vascular diseases and is recommended generally after all conventional medical or surgical options have been exhausted. After a widely publicized start in 1967, poor results were observed over the ensuing decade. In the 1980s, however, the field of cardiac transplantation experienced dramatic growth (Table 56.1) because of significant improvements in outcome, probably most directly related to immunosuppressive therapy and to refinements in diagnosis and treatment of rejection episodes [38]. Mechanical pumps, such as implantable ventricular assist devices or the bioartificial heart, have contributed to this success because they can also serve as a bridge during the time between end-stage cardiac failure and a transplantation.

Heart–Lung and Lung

Heart–lung and lung transplants are an effective treatment for patients with advanced pulmonary parenchymal or vascular disease, with or without primary or secondary cardiac involvement. This field has evolved rapidly since the first single-lung transplant with long-term success was performed in 1983 (Table 56.1). The significant increase in lung transplantations is mainly due to technical improvements resulting in fewer surgical complications, as well as to the extremely limited availability of heart–lung donors. Previously, many patients with end-stage pulmonary failure would have waited for an appropriate heart–lung donor. Now, they undergo a single or a bilateral single-lung transplant instead [39]. Bilateral single-lung transplants are specifically indicated in
patients with septic lung diseases (e.g., cystic fibrosis, $\alpha_1$-antitrypsin deficiency) in which the remaining native contralateral lung could cross-contaminate a single transplanted lung. Double en bloc lung transplants have been abandoned because of technical difficulties related to the bronchial anastomotic blood supply. Mechanical ventilation or extracorporeal membrane oxygenation (ECMO) can be used as a temporary bridge to this type of transplant, but none of these modalities obviates the need for organ replacement therapy.
CURRENT STATUS OF ORGAN DONATION

Current organ supply does not meet demand. This is due to an insufficient augmentation of the donor pool (Tables 56.1 and 56.2; Fig. 56.1). The 55-mile-per-hour speed limit, stricter seat belt and helmet laws, advances in critical care, as well as the trend toward a deceleration of care in patients that have suffered a catastrophic brain injury have all had significant impacts on the number of brain-dead organ donors [1]. In 2016, the three leading causes of death among deceased donors in the United States were cerebral anoxia (e.g., due to a cardiac arrest), a cerebrovascular accident (e.g., due to a stroke or an intracranial aneurysmal bleed), and traumatic brain injury [1,2].

A positive trend is the increasing number of DCD donors (Fig. 56.1) [2,24]. These donors constitute currently nearly 20% of the overall deceased donor pool [2]. In DCD donors, refined surgical techniques allow for fast insertion of cannulas and perfusion of vital organs while these are rapidly excised. Innovative approaches, such as withdrawal of support technologies in the ICU (rather than in the operating room), in the presence of the donor’s family, may further increase acceptance of DCD donation among potential donors’ families and health care professionals [26,29]. Moreover, ongoing refinements of organ perfusion and preservation techniques, including maintenance of the DCD donor on ECMO until organ recovery can occur, and placement of the recovered organs on hypothermic or normothermic perfusion using a pump during the transport and preservation phase, all result in less ischemic organ injury and also allow for better organ preservation and increased utilization of DCD donor organs [24,40–43]. Currently, kidneys and livers are the organs most commonly recovered and transplanted from DCD donors [2].

According to estimates, there are at least 10,500 to 13,800 potential brain-dead donors in the United States per year [12]. In 2016, however, there were only 9,971 actual deceased organ donors in the United States [1]. According to a study, the overall consent rate (the number of families agreeing to donate divided by the number of families asked to donate) was 54% in the United States, and the overall conversion rate (the number of actual donors divided by the number of potential donors) was 42% [12]. The single most important reason for lack of organ recovery from 45% to 60% of the potential donor pool is the inability to obtain consent [12,24]. Several studies have shown that family refusal to provide consent and the inability to identify, locate, or contact family members to obtain consent within an appropriate time frame are the leading causes for the nonuse of many organs from potential donors [10–13,24]. A
public opinion survey showed that 69% of respondents would be very or somewhat willing to donate their organs, and 93% would honor the expressed wishes of a family member [44]. However, only 52% of these individuals had communicated their wishes to their family. Moreover, 37% of respondents did not comprehend that a brain-dead person should be considered dead and unable to recover, and 59% either believed or were unsure whether or not organs can be bought and sold on the “black market.” Also, 42% did not realize that organ donation does not cause any financial cost to the family of the deceased in the United States [44]. Finally, racial differences which are likely based on historical distrust in the health care system may adversely impact donation rates as well. For instance, African American families have been consistently found to be less willing to consent to organ donation than White families [45].

Correcting these misperceptions and attempting to increase awareness of the importance of organ transplantation must remain the focus of public educational campaigns [24,29]. The family’s knowledge of the patient’s previous wishes is central to decision-making [10,11,13]. Such efforts can be successful, especially among minorities, in whom mistrust and the perception of inequitable access to medical care and organ transplant therapy have led to disappointingly low organ donation and recovery rates [24,45]. It is very important that adequate communication, empathy, and an informative, humane approach to the family of the deceased occur to ensure reasonable consideration of donation. Families are more likely to donate if they are approached by an OPO coordinator, view the requestor as sensitive to their needs, and experience an optimal request pattern [11,13,22]. Educational efforts to enhance organ donation must therefore also be directed at health care professionals and medical students, whose views and knowledge of these issues are often inconsistent and limited [29,46]. Physicians, too, need to be better trained to recognize and refer potential organ donors and to not discuss organ donation until a member of the local OPO has approached their families [11,13,22]. As a result, since 1998, Conditions of Participation of the Centers for Medicare and Medicaid Services (CMS) require hospitals to use “designated requestors” to obtain family authorization. Finally, the potential for financial compensation or other rewards for deceased donor families (e.g., compensation for funeral expenses) has been considered as a means to increase donation rates [46]. But the potential effects of such an intervention on donation rates remain unclear.
OTHER OPTIONS TO INCREASE ORGAN AVAILABILITY

Additional mechanisms that might help to increase the number of available organs for transplantation include (a) optimization and maximal use of the current actual donor pool; (b) increasing the number of living donor transplants, including the provision of incentives for live donation; (c) enacting presumed consent laws; (d) allowing the use of organs from executed prisoners; and (e) xenotransplants (e.g., use of animal organs as a potentially unlimited supply for transplantation into humans, particularly after genetic engineering). Only the first two options are, however, of practical interest at this time.

Optimal use of the Current Donor Pool

As a result of the ongoing organ shortage, transplant surgeons have attempted to refine procurement techniques so that maximal use of the available donor pool occurs (Fig. 56.2) [47]. On average, more than three organs are recovered and transplanted from each deceased donor (Fig. 56.2) [1,2].

![Transplant rates (by organ) from 8,085 deceased donors (100%; 2007) in the United States. The last bar represents the mean number of organs transplanted per deceased donor for the year 2013. Tx’d, transplanted; Dec., deceased. (Based on data from references [1,2])](image-url)
Marginal donors—elderly patients, patients with a history of hypertension, poisoning victims, patients with significant organ injury (e.g., liver laceration due to blunt injury) or complications of brain death (e.g., hypotension, acute kidney injury with oliguria or anuria, disseminated intravascular coagulation)—are routinely used for recovery of kidneys and extrarenal organs \[1,2,24\]. Organ recovery techniques also have been adapted to facilitate use of older donors with significant aortic atherosclerosis \[48\]. The increased use of hypothermic machine perfusion of kidney grafts allows to assess the quality of grafts from marginal donors and facilitates—by improving preservation quality—organ allocation to geographically more distant transplant centers \[42\].

Organs with anatomic abnormalities (e.g., multiple renal arteries or ureters, horseshoe kidney, annular pancreas) also are being used routinely. Improvements in operative technique permit the \emph{en bloc} transplantation of two kidneys from very young (e.g., infant) donors that would have been too small to be used separately in one recipient \[49–51\]. Similarly, transplantation of both kidneys from an \emph{adult} donor into one recipient is, on occasion, done to avoid discarding suboptimal kidneys with an insufficient individual nephron mass. To maximize the use of livers, adult donor livers can be split and the two size-reduced grafts transplanted into two recipients (e.g., a pediatric and an adult recipient). A similar principle has also been proposed for the pancreas and has been reported on at least one occasion \[52\].

Explanted livers from patients undergoing liver transplantation for hepatic metabolic disorders that cause systemic disease without affecting other liver functions (e.g., familial amyloidotic polyneuropathy, hereditary oxalosis) can be used for transplanting other patients ("domino transplant") who are not candidates for deceased livers because of graft shortage (e.g., cirrhotic patients with hepatocellular carcinoma confined to the liver who are not in the group with good expected survival) \[53\]. The combination of split-liver and domino transplantation can even result in transplantation of three adult patients with one deceased donor graft \[54\].

The advent of single-lung transplants has made it possible to distribute the heart and lungs of one donor to three recipients. Formerly, transplanting a heart–lung bloc into one recipient was the treatment of choice for end-stage pulmonary disease. If the native heart of a heart–lung recipient is healthy, a domino transplant can be performed: The heart–lung recipient donates his or her heart to another patient in need of a heart transplant.

In an attempt to optimize use of scarce donor resources, the reuse of previously transplanted hearts, kidneys, and livers has also been reported. However, all these methods allow only for better use of organs from the existing donor pool. The cornerstone for an effective increase in
the number of organ donors remains heightened awareness and education of the public, physicians, and other health care professionals to improve consent and conversion rates [11–13,24,29].

**Living Donors**

The use of organs from living donors, traditionally limited to kidney transplants, has been expanded to the liver, small bowel, pancreas, and lung [1,2]. In the more distant past, most living donors were genetically related to the recipient—siblings, parents, and adult children. As a result of the organ shortage, the use of living unrelated kidney donors, who are emotionally, but not genetically, related to the recipient (e.g., spouses, close friends), or are emotionally and genetically unrelated to the recipient (i.e., nondirected, “Good Samaritan” donors), has considerably increased over the past 25 years (Fig. 56.1) [1,2,55]. In order to increase the number of live donor transplants even further, paired-kidney-exchange programs and living donor chain transplants have been implemented [56,57]. In that setting, the supply of organs is increased for instance by exchanging kidneys from living donors who are ABO or crossmatch incompatible with their intended recipients, but ABO or crossmatch compatible with another donor–recipient pair (donor A would provide a kidney to [ABO or crossmatch compatible] recipient B, and donor B would provide a kidney to [ABO or crossmatch compatible] recipient A) [56,57]. In cases when paired-kidney-exchange or donor chain transplants are not available or feasible, it is alternatively possible to precondition (desensitize) the intended recipient of an ABO or crossmatch incompatible kidney (by use of plasmapheresis and/or intravenous immunoglobulin and pharmacologic intervention) to still facilitate a successful living donor kidney transplant.

Currently, there is considerable public debate on providing incentives for living kidney donation [58–61]. The debate centers on concerns that reimbursement might lead to the commercialization of organ donation, with the inherent risk of turning potential donors and transplantable organs into a commodity [59,60]. In the United States, those in support of compensating live donors stress that an Organ Procurement and Transplantation Network–run transparent system of paid living donation would ensure that donors are compensated fairly, eliminate transplant tourism to other countries, greatly diminish the currently existing black market for organs in those countries, and emphasize any potentially interested donor’s autonomy—while at the same time increasing the organ supply [58,61]. In any case, paid living donation, while a reality in certain regions of the world, remains currently unlawful in the United States and most Western countries. Even when assuming that (i) public attitudes toward living donation will continue to evolve favorably (Fig.
(ii) innovative approaches as described above will be increasingly used, and (iii) other alternative means for finding living donors, such as donor solicitation via social media, would ultimately prove to be successful, only modest increases of the absolute number of living kidney donors could be expected [58–63]. Finally, compared with renal transplantation, the proportion of living donor transplants for extrarenal organs is much smaller (less than 5% for liver and less than 0.5% for pancreas, lung, and small bowel) [1]. Thus, living donor transplants will continue to help alleviate the organ shortage for certain organs (kidney, liver) to some extent, but will never be able to completely compensate—even under the best circumstances—for the severe lack of deceased donors.

Presumed Consent Laws

Presumed consent laws have been implemented in many areas of the world, most notably in several countries in Europe. These laws permit organ procurement unless the potential donor has objected explicitly. A permanently and easily accessible registry of objectors is a prerequisite for such a system. In the United States, proposals for presumed consent legislation have not had broad support. Moreover, presumed consent would not alleviate the problem of insufficient donor identification and referral [12].

The beneficial impact that such laws can have became evident in Spain. In that country, presumed consent laws coupled with the creation of a decentralized network of mostly hospital-based, specifically trained transplant coordinators (most of them physicians in intensive care units) in the early 1990s led not only to more efficient identification of eligible deceased donors but also to higher consent rates. Accordingly, the annual donation rate in Spain rose from 14.3 donors per million population (pmp) in 1989 to 34.2 pmp in 2008 (United States, 2008: 26.3 pmp) [64–66]. Interestingly, a similar approach (without the presumed consent component) using in-house coordinators at some hospitals in the United States did yield greater consent and conversion rates, too, and underscored the advantages that such a system could have, if implemented at a larger scale [67].

Organs from Executed Prisoners

Certain countries (e.g., China) routinely use organs from executed prisoners. This practice has been strongly rejected by the national and
international transplant community [68]. Moreover, proposals to use organs from executed prisoners would engender a very passionate, emotional debate that would have a negative impact on public opinion and thereby decrease overall organ availability.

Xenotransplantation

Xenotransplantation of organs and tissues from animals into humans offers a potentially unlimited supply of donors [68,69]. Past attempts have received significant public attention [69], but numerous practical problems remain before this procedure could become a clinical reality. Ethical concerns regarding the use of animal organs for transplantation have also been raised. Immunologic concerns include hyperacute rejection (mediated by circulating, preformed natural antibodies), which occurs in vascularized solid organ transplantation between virtually all discordant species. Also, the biocompatibility of protein synthesized by an animal liver and the human organism is not fully established, and infectious diseases (e.g., caused by porcine endogenous retroviruses) could be transmitted when using nonhuman primates or pigs as donors. Genetic engineering of animals before their use as donors to overcome the immunologic barriers is an area of intensive investigation. Significant experimental progress in this area could fundamentally change the field of organ transplantation.
REGULATION AND ORGANIZATION OF ORGAN PROCUREMENT AND ALLOCATION

In the early 1980s, the introduction of new immunosuppressive agents engendered a rise in organ transplant activity. Tissue matching (e.g., by use of living related donor–recipient combinations) became less important, and the use of brain-dead donors increased (Fig. 56.1). In the wake of these developments, consolidation and national regulation of the organ sharing and allocation organizations, which had previously functioned mainly at a local and regional level, became necessary.

In the United States, the National Organ Transplant Act of 1984 called for a national system to ensure equitable access to transplant therapy for all patients, a major component of which was fair organ allocation. The federal government commissioned a task force on organ transplantation to define such an allocation system. This task force, whose members were appointed by the U.S. Department of Health and Human Services, resolved that human organs are a “national resource to be used for public good” and recommended the creation of a national Organ Procurement and Transplantation Network (OPTN) [3]. In 1986, the U.S. Department of Health and Human Services awarded the OPTN contract to the United Network for Organ Sharing (UNOS). Pursuant to the contract, UNOS was asked to design a network to achieve balance in the goals of equity in organ access and distribution and in optimal medical outcome [70]. In 1986, the Omnibus Budget Reconciliation Act mandated that only hospital members of the OPTN could perform Medicare- and Medicaid-reimbursed transplant procedures. In 1988, the Organ Transplant Amendments reaffirmed the federal interest in equitable organ allocation by locating authority in UNOS as opposed to local transplant organizations.

The national OPTN is currently operated under contract by UNOS, which is accountable to the U.S. Department of Health and Human Services. All patients on waiting lists of a transplant program are registered with UNOS, which maintains a centralized computer system linking all OPOs and transplant centers. The United States has been divided into 11 regions for organ procurement, allocation, and sharing purposes (Fig. 56.3). Organs are registered, shared, and allocated through use of the central UNOS computer, which generates a list of recipients for each available organ. Patients awaiting deceased donor transplantation are ranked according to UNOS policies, based on medical and scientific criteria that—depending on the organ—may include blood type, tissue type, length of time waiting on the list, age (pediatric vs. adult), level of
presensitization (percentage of panel reactive antibody), and medical status. For kidneys, national sharing of virtual crossmatch compatible, very highly sensitized recipients is mandated. For the vast majority of all of the other organs, though, allocation first takes place locally and then regionally. If no suitable recipients are available, organs are then allocated nationally.

**FIGURE 56.3** United Network for Organ Sharing (UNOS) regions in the United States (24-hour access number: 1-800-292-9537). The United States has been divided into 11 regions for organ procurement, allocation, and sharing purposes.
LEGAL ASPECTS OF ORGAN DONATION AND BRAIN DEATH

Uniform Anatomical Gift Act

The Uniform Anatomical Gift Act, adopted in 1968 and in force throughout the United States, allows any adult individual (over age 18 years) to donate all or part of their body for transplantation, research, or education. This act also provides the legal basis for recovery of organs from both DCD and brain-dead (vide infra) donors. Explicit consent is required. The act also specifies who may give consent (e.g., legal next of kin) for donation [71].

The 2006 Revised Uniform Anatomical Gift Act honors the choice of an individual to be or not to be a donor and strengthens the language barring others from overriding a donor’s first-person authorization to make an anatomical gift. The revised act also empowers minors that apply for a driver’s license to become donors and encourages and establishes standards for donor registries [72].

Uniform Determination of Death Act

Over the past five decades, brain death has legally become equated with death in most Western developed countries. Brain death means that all brain and brain stem function has irreversibly ceased. The recognition of brain death became possible only after substantial advances in intensive care medicine (e.g., provision of cardiovascular support, prolonged mechanical ventilation). The first classic description of brain death was published in 1959 in France and termed coma dépassé (beyond coma). An ad hoc commission of the Harvard Medical School defined brain death criteria in the United States in 1968 [73]. These criteria were judged by some as being too extensive and too exclusive. In 1981, the President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research formulated the Uniform Determination of Death Act, which established a common ground for statutory and judicial law related to the diagnosis of brain death. The commission stated that “an individual who has sustained . . . irreversible cessation of all functions of the entire brain, including the brainstem, is dead,” and left the criteria for diagnosis to be determined by “accepted medical standards.”

Those standards were defined in a related report to the President’s Commission on the diagnosis of death by 56 medical consultants in 1981.
The guidelines in that report have now been accepted as the standard for determining brain death in the United States. They are as follows: “Cessation is recognized when: (1) all cerebral functions and (2) all brainstem functions are absent. The irreversibility is recognized when: (1) the cause of the coma is established and is sufficient to account for the loss of brain functions, (2) the possibility of the recovery of any brain functions is excluded, and (3) the cessation of cerebral and brainstem function persists for an appropriate period of observation and/or trial of therapy” [74]. Confusion regarding this well-founded and accepted medicolegal concept of the equivalence of brain death and death of a human persists to this date among physicians, other health care professionals, and the general public [11,13]. Specifically, in the field of transplantation, it should be unequivocally clear to the potential donor’s family and anyone involved in the patient’s care that the time of death is the time at which the diagnosis of brain death is established and not the time of cardiac arrest during the organ recovery. Providing education targeted specifically at these groups and society at large is of paramount importance to optimize consent rates [11,13].

**Required Request**

Required request laws have now been enacted in all states in the United States. They obligate hospitals to notify an OPO of potential donors and to offer the option of donation to the families of potential donors (brain-dead and DCD donors). In order to optimize this process, the CMS’ Conditions of Participation have been requiring hospitals since 1998 to use “designated requestors” to obtain authorization from legal next of kin for donation [75].

**Clinical Diagnosis of Brain Death**

The clinical diagnosis of brain death rests on three criteria: (a) irreversibility of the neurologic insult, (b) absence of clinical evidence of cerebral function, and, most important, (c) absence of clinical evidence of brain stem function (Table 56.4) [76–79]. Irreversibility is established if structural disease (e.g., trauma, intracranial hemorrhage) or an irreversible metabolic cause is known to have occurred. Hypothermia, medication side effects, drug overdose, and alcohol ingestion and intoxication must be ruled out when testing for brain death. Plasma concentrations of sedative or analgesic drugs sometimes correlate poorly with cerebral effects. Therefore, residual effects of those drugs can be excluded only by passage of time, if any doubts exist. As no evidence-based recommendations for a minimal waiting time prior to the first brain death examination can be made, good—individualized—clinical judgment is paramount. The observation period between two sequential
Brain death examinations should be at least 6 hours for structural causes and preferably 12 to 24 hours for metabolic causes, drug overdose, or intoxication [76–79]. Even with potentially reversible metabolic alterations (e.g., hepatic or uremic encephalopathy), recovery has not been described after duration of the brain death state for more than 12 hours and as long as all criteria in Table 56.4 (which are based on the 1995 American Academy of Neurology medical standards for death determination using neurologic criteria and on its 2010 update) are met [77, 78]. Clinical testing of cerebral and brain stem function is detailed in Table 56.4 [76–81]. Although pediatric donors are not the focus of this chapter, it should be noted that brain death criteria are more stringent for very young pediatric patients, particularly newborns, in whom criteria for brain death also include demonstration of the absence of blood flow on cerebral flow studies.

### Table 56.4 Brain Death Criteria and Clinical Diagnosis of Brain Death

<table>
<thead>
<tr>
<th>Irreversible, well-defined etiology of coma</th>
</tr>
</thead>
<tbody>
<tr>
<td>Structural disease or metabolic cause (requires documentation by neuroimaging)</td>
</tr>
<tr>
<td>Exclusion of: significant hypothermia (defined as core temperature &lt;33°C); hypotension (systolic blood pressure must be &gt;100 mm Hg); severe electrolyte, endocrine, or acid–base disturbance; and drug, alcohol or substance intoxication (may require toxicology screen; barbiturates, if present, serum level must be &lt;10 μg/mL)</td>
</tr>
<tr>
<td>No spontaneous respirations</td>
</tr>
<tr>
<td>Absence of residual paralyzing agents</td>
</tr>
<tr>
<td>Sufficient observation period (at least 6 h) between two brain death examinations</td>
</tr>
<tr>
<td>No clinical evidence of cerebral function</td>
</tr>
<tr>
<td>No spontaneous movement, eye opening, or movement or response after auditory, verbal, or visual commands</td>
</tr>
<tr>
<td>No movement elicited by painful stimuli to the face and trunk (e.g., sternal rub, pinching of a nipple or fingernail bed) other than spinal cord reflex movements</td>
</tr>
<tr>
<td>No clinical evidence of brain stem function</td>
</tr>
<tr>
<td>No pupillary reflex: pupils are fixed and midposition; no change of pupil size in either eye after shining a strong light source in each eye sequentially in a darkened room</td>
</tr>
<tr>
<td>No corneal reflex: no eyelid movement after touching the cornea (not the conjunctiva) with a sterile cotton swab or tissue</td>
</tr>
</tbody>
</table>
No gag reflex: no retching or movement of the uvula after touching the back of the pharynx with a tongue depressor or after moving the endotracheal tube

No cough reflex: no coughing with deep tracheal irrigation and suctioning

No oculocephalic reflex (doll’s eyes reflex): no eye movement in response to brisk turning of the head from side to side with the head of the supine patient elevated 30 degrees

No oculovestibular reflex (caloric reflex): no eye movements within 3 min after removing earwax and irrigating each tympanic membrane (if intact) sequentially with 50 mL ice water for 30 to 45 seconds while the head of the supine patient is elevated 30 degrees

No integrated motor response to pain: no localizing or withdrawal response (face; all four limbs), no extensor or flexor posturing

No respiratory efforts on apnea testing (PaCO₂ >60 mm Hg or 20 mm Hg higher than the normal baseline value): The patient is preoxygenated with an FiO₂ of 1.0 for 10–15 minutes to reach a PaO₂ >100 mm Hg (preferably with an arterial line in place for rapid blood gas measurements) while adjusting ventilatory rate and volume such that the PaCO₂ reaches ~40–45 mm Hg. After a baseline arterial blood gas value is obtained and the patient is disconnected from the ventilator, O₂ at 6–8 L/min is delivered through a cannula advanced 20–30 cm into the endotracheal tube (cannula tip at the level of the carina). Continuous pulse oximetry is used for early detection of desaturation, which does not usually occur when using this protocol. In most cases, a PaCO₂ >60 mm Hg is achieved within 3–5 minutes after withdrawal of ventilatory support; at this point, the patient should be reconnected to the ventilator (or earlier, should hemodynamic instability, desaturation, or spontaneous breathing movements occur). Obtaining an arterial blood gas sample immediately before reinstitution of mechanical ventilation is mandatory. If there is no evidence of spontaneous respirations before reinstitution of mechanical ventilation in the presence of a PaCO₂ >60 mm Hg or an increase of >20 mm Hg from the normal baseline value, the criteria for a positive apnea test are met.

Other points

Spinal reflexes, such as deep tendon reflexes and triple flexion responses, can be preserved and do not exclude the diagnosis of brain death

Shivering, piloerection, arm movements, reaching of the hands toward the neck, forced exhalation, and thoracic respiratory-like movements are possible after brain death and are likely to release phenomena of the spinal cord, including the upper cervical cord. All these findings are compatible with the diagnosis of brain death.

Confirmatory tests should be used in cases in which the observation period needs
to be shortened (e.g., unstable donors), if the apnea test had to be aborted in equivocal situations in children younger than 1 year old, or if one of the potential pitfalls (Table 56.6) cannot be ruled out (demonstration of absence of intracranial circulation by conventional cerebral angiogram, Tc-99m hexamethylpropyleneamine oxime single photon-emission computed tomography, transcranial Doppler ultrasonography, or electrocerebral silence documented by an electroencephalogram).

References [76–80].

After brain death, the pupils become fixed in midposition because sympathetic and parasympathetic input is lost. Decerebrate (abnormal extension) and decorticate (abnormal flexion) responses to painful stimuli imply the presence of some brain stem function and are incompatible with the diagnosis of brain death. In contrast, spinal cord-mediated tendon reflexes, automatic stepping, and other complex motor activities (which can also occur during apnea testing) are compatible with brain death [78,79,82]. The occurrence of these movements can be quite distressing if observed by the next of kin; therefore, it is advisable that they not be present during the apnea test. Very rarely, ascending acute reversible inflammatory polyneuropathy (Guillain–Barré syndrome) can simulate brain death and inhibit all motor functions, including pupillary reactions and brain stem reflexes. The typical clinical history, coupled with evidence of progressive weakness, should yield the correct diagnosis and preclude a diagnosis of brain death from being established [76–79].

The American Academy of Neurology has stated that special confirmatory tests are not necessary to diagnose brain death in the vast majority of cases. Only in equivocal or questionable circumstances does a study demonstrating the absence of intracranial blood flow need to be performed [76–78]. The most sensitive and specific test for assessing intracranial blood flow is four-vessel catheter cerebral arteriography. Alternatively, Tc-99m hexamethylpropyleneamine oxime single photon-emission computed tomography may be used [78,80]. Other ancillary tests are either less sensitive (e.g., digital subtraction angiography, transcranial Doppler ultrasonography), less specific (e.g., brain stem acoustic evoked potentials), or measure only hemispheric flow.

Four-vessel cerebral catheter arteriography is indicated in all conditions that can temporarily cause an isoelectric electroencephalogram (e.g., extreme intoxication). If the indication for cerebral arteriography is unclear, the benefits must be weighed against the potential risks of transporting an unstable patient. Confirmatory tests may serve to shorten the waiting period between the two brain death examinations, should donor hemodynamic instability occur. Certain
potential pitfalls exist in clinical brain death testing, and the diagnosis should not be considered to have been established until these all have been excluded (Table 56.5) [79]. If these cannot be excluded, confirmatory testing is mandatory [79,80].

suppressive side effects on the vestibular system (e.g., tricyclic antidepressants, anticonvulsants, and barbiturates) or due to preexisting disease.

If one of the listed conditions cannot be ruled out, confirmatory testing (cerebral flow studies or electroencephalography) is necessary before brain death is declared.

In summary, the diagnosis of brain death can be established by performance of routine neurologic examinations, including cold caloric and apnea testing on two separate occasions, coupled with prior establishment of the underlying diagnosis and prognosis in most cases [76–80]. More sophisticated tests are required in cases in which the diagnosis cannot be unequivocally established [78,80]. However, brain death must be diagnosed in accordance with local regulations and state laws. Details on the locally prevailing regulations are available through the state medical board and the local OPO.
ORGAN DONATION PROCESS

The three key elements leading to successful organ donation are (a) early referral of potential donors, (b) a well-coordinated approach in informing and dealing with the potential donor’s family to request and obtain consent, and (c) appropriate critical care therapy of the donor [11,13]. The optimal course of events for both brain-dead and DCD donors is summarized in **Table 56.6**.

**TABLE 56.6 Organ Donation Algorithm**

1. Early identification of the potential donor by the critical care physician or health care professional (Table 56.3).
2. Early contact with the local or regional OPO for medical, legal, and logistic assistance. If the local OPO’s address or phone number is unknown, a 24-h access number to UNOS is available: 1-800-292-9537.
3. Completion of the preliminary screening by the OPO if necessary in consultation with the transplant surgeon for decisions regarding marginal donors.
4a. For potential DCD donors: await family decision regarding withdrawal of care. Proceed only if family decides to do so.
4b. For potential brain-dead donors: brain death diagnosis and confirmation (Tables 56.4 and 56.5), certification of death. Family notification and explanation of brain death with its legal and medical implications. Sufficient time for acceptance must be allowed.
5. Request for organ donation. Must be made after, and in clear temporal separation, from step 4a or 4b.
6. After consent for organ donation is obtained, the focus switches from treatment of elevated intracranial pressure and cerebral protection to preservation of organ function and optimization of peripheral oxygen delivery (Table 56.8).
7. All remaining laboratory and serologic studies as well as any further studies and tests required in equivocal situations are performed at this point.
8. Final organ allocation by the OPO and UNOS, coordination of the organ recovery operation, notification of the abdominal and thoracic surgical teams. Modification of the final steps may become necessary under special circumstances, for example, in hemodynamically unstable donors.
9. For controlled DCD donors: Support is withdrawn and death is certified (in the ICU or in the operating room).

10. Organ recovery operation (brain-dead and DCD donors).

OPO, organ procurement organization; UNOS, United Network for Organ Sharing; DCD, donation after circulatory death.
Steps 4, 5, and 9 should not involve physicians who are part of the transplantation team.

**Early Donor Referral**

Early referral of any potential donor to the local OPO minimizes the loss of transplantable organs due to unexpected cardiac arrest and death, hemodynamic instability, serious nosocomial infection, or complications related to intensive care [83,84]. For example, an inverse correlation exists between the duration of mechanical ventilation and the suitability of the donor for lung donation.

The evidence is substantial that brain death eventually leads to cardiac arrest, even when cardiorespiratory support is maintained [83,84]. Cardiac arrest occurs in 4% to 28% of potential donors in the maintenance phase, and as many as 50% of all potential donors die within 24 hours without appropriate support [83,84].

The previously outlined clinical triggers for early referral to the local OPO should therefore be applied to any neurologically severely injured patient after admission to the hospital or intensive care unit (Table 56.3). Early contact with the OPO is essential as the latter will provide assistance with further screening and the evaluation of any patient who might potentially become a donor.

**Donor Evaluation**

**General Guidelines.** During the initial contact with the OPO, the physician should provide the potential donor’s name, age, sex, height, weight, and blood type. Also needed are the date of admission and diagnosis, the nature and extent of any trauma, a concise medical and social history, and the time of brain death (if applicable). Whether local investigative agencies (e.g., medical examiner, coroner) need to be notified also should be specified. The current medical status, including vital signs, urine output, cardiorespiratory status, medications, and culture results, must be communicated. Basic laboratory results should be obtained: arterial blood gas determinations; blood urea nitrogen, creatinine, and electrolyte values; hemoglobin, hematocrit, white blood cell and platelet counts, and tests for serum amylase, total bilirubin, alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase; coagulation profile (including prothrombin time or
International Normalized Ratio); and urinalysis and urine culture, along with electrocardiogram and chest radiograph results. In the case of potential lung donors, chest circumference and radiographic thoracic measurements, as well as the results of an oxygenation challenge (partial arterial oxygen pressure \([\text{PaO}_2]\) measurement after ventilation for 10 minutes with a fraction of inspired oxygen \([\text{FiO}_2]\) of 1.0), are helpful.

The OPO provides further procedural, administrative, legal, and logistic help. Most importantly, the OPO coordinates how the family is approached. All further testing (including human leukocyte antigen tissue typing; serologic screening for cytomegalovirus [CMV], for hepatitis A, B, and C viruses [HAV, HBV, HCV], for human immunodeficiency virus [HIV], and syphilis; and blood, sputum, and urine cultures) is then coordinated through the OPO if the donor passes the preliminary screening tests. The organ allocation process begins only after the family has decided to withdraw support technologies (DCD donors) or brain death has been declared and consent has been obtained. If prospective tissue typing is to be done, it may occasionally be necessary to perform a bedside surgical inguinal lymph node biopsy at the donor hospital—after consent for organ donation has been obtained, but before proceeding with the actual organ recovery several hours later.

The medical status and the life expectancy of the potential recipient without the organ transplant are taken into account when considering the risks associated with a specific donor’s medical characteristics and the final decision about transplantation of a specific donor organ is made. The ultimate decision regarding the use of a donor organ is made by the transplant surgeon. At this stage, the transplant center may need to obtain further tests to assess the functional status of one or more organ systems. For example, if the heart is to be recovered, an echocardiogram is usually obtained. In selected donors, coronary angiography is performed. Pulmonary status can be further assessed by bronchoscopy after considering the results of the chest radiograph, oxygenation challenge, and sputum cultures. For potential liver donors who might have fatty liver disease, a percutaneous bedside liver biopsy can be performed. If concern over the suitability of organs arises, direct inspection by the transplant surgeon is necessary at the time of the organ procurement operation. In some cases, an open biopsy (e.g., for kidney or liver) and frozen section pathologic analysis obtained at the time of organ recovery also help in the final decision-making. Direct inspection also is important in organ donors who suffered a blunt injury to the head and trunk (e.g., motor vehicle accident). Under these circumstances, intraabdominal organs have been used successfully despite the presence of parenchymal tears or subcapsular hematomas in either the liver or the kidney. Significant injuries to the pancreas preclude its use.

In summary, each patient with a severe nonrecoverable neurologic
injury should be referred to the local OPO as a potential donor, regardless of the type of brain injury (e.g., trauma, stroke), history, age, or medical condition (Table 56.3). With few exceptions (vide infra), organ donation should never be excluded a priori because of the clinical situation, the results of imaging studies, or the magnitude of an injury, without first having contacted the local OPO (24-hour access number: 1-800-292-9537).

**Organ-Specific Considerations.** The use of kidneys from older donors, donors dying of cardiovascular disease, or donors requiring large doses of inotropic drugs for cardiovascular support entails a higher rate of delayed graft function and is associated with decreased graft survival [85,86]. Nevertheless, organs from these marginal donors are routinely used given the current prolonged periods (which can be longer than 8 to 10 years in some areas) that some recipients may wait for available organs, during which their medical condition may deteriorate. Marginal donor kidneys benefit from preservation on a pulsatile perfusion pump, which was shown to improve preservation quality, quality of early graft function, and long-term outcomes [42]. In equivocal cases (e.g., donors with elevated baseline serum creatinine levels or a history of hypertension), renal biopsies at the time of organ recovery may quantify the amount of preexisting donor arteriosclerosis or glomerulosclerosis. The critical shortage of organs has led to increasing relaxation of exclusion criteria, with satisfactory long-term results in many recipients.

Livers from donors with an abnormal liver enzyme or coagulation profile can frequently still be transplanted. Elevated hepatic enzyme levels may reflect transient hepatic ischemia at the time of resuscitation. The trends observed in the results of serial hepatic enzyme levels can be more informative than absolute values. Abnormal coagulation test results may be due to disseminated intravascular coagulation (commonly a result of brain injury, not primary hepatic dysfunction). Significant donor hypernatremia (e.g., >155 mg per dL), as commonly observed in under-resuscitated brain-dead donors with significant diabetes insipidus, may be a risk factor for primary liver graft nonfunction posttransplant. Aggressive intervention prior to procurement is warranted and will ultimately allow for safe transplantation of liver grafts from these hypernatremic donors. The decision to use a liver from a marginal donor has to be made on the basis of relatively limited information. Often, only direct inspection, with or without a biopsy of the liver, at the time of organ recovery provides a final answer and may be the only way to assess a donor with a history of significant ethanol intake. Severe
macrovesicular hepatic steatosis is one of the most significant factors predictive of early posttransplant hepatic dysfunction or failure.

In general, donors older than 60 years of age are not considered for pancreas donation. However, donors with hyperglycemia [caused by peripheral insulin resistance, particularly after brain death (see the section “Endocrine Therapy”) or with hyperamylasemia (which can be a consequence of severe head injury without actual pancreatitis)] are not to be excluded a priori from pancreas donation, because these factors do not necessarily influence posttransplant outcome [87,88]. A pancreas transplant registry analysis suggested a slightly higher incidence of graft thrombosis for pancreata that had been procured from donors treated with desmopressin (vs. those that did not) [89]. Clearly, further study is necessary to confirm or refute these findings and determine their clinical significance. Currently, the only absolute contraindications to pancreas donation are a history of impaired glucose tolerance or insulin-dependent diabetes mellitus, direct blunt or penetrating trauma to the pancreas, or the finding of acute or chronic pancreatitis at the time of the donor operation.

Regarding heart donation, an important criterion is good donor heart ventricular function immediately before retrieval, as judged by the cardiac surgeon at visual inspection during organ recovery. Ideally, no potential heart donor should be excluded solely on the basis of echocardiographic wall motion abnormalities, a borderline or abnormal ejection fraction, inotropic medication requirements, or heart murmurs, arrhythmias, or other electrocardiographic changes (which often occur in brain-dead individuals in whom no cardiac disease is present).

Risk factors associated with poorer outcomes after lung transplantation include a history of smoking, aspiration, purulent secretions observed during bronchoscopy, an abnormal chest radiograph, or an unsatisfactory oxygenation challenge (PaO$_2$ less than 300 mm Hg after 10 minutes of ventilation with FiO$_2$ of 1.0 and low positive end-expiratory pressure [PEEP] of 5 cm H$_2$O) alone or in combination in lung donors. However, even lungs with these characteristics have been successfully transplanted [90]. Bronchoscopy often is performed as a final preoperative confirmatory test in the operating room by the lung recovery surgeon. Direct intraoperative inspection of the lungs determines whether significant contusions are present, which could preclude use of the organs.

In conclusion, the traditional donor criteria have been considerably expanded over recent years, for both thoracic and abdominal organs, due to the ongoing, severe donor shortage.

**Transmission of Infectious Diseases.** Transmission of bacterial or fungal infection through organ transplantation can potentially be due to
an infection of the donor or contamination of the organ itself during organ procurement or storage. Published evidence suggests that organs transplanted from bacteremic donors and from donors with bacterial meningitis do not transmit bacterial infection or result in poorer recipient outcomes provided that donor and recipient(s) are adequately treated with antibiotics [91]. Similarly, positive urine cultures do not preclude renal donation and transplantation. Organs from donors with serologic evidence of syphilis can be used as long as the recipients are given adequate antibiotic prophylaxis.

Seropositivity for HIV no longer constitutes an absolute contraindication to organ donation, as the federal ban on transplantation of organs from HIV-positive individuals has been lifted [92]. As of late 2015, transplant hospitals that meet specific criteria set forth by the OPTN can consider HIV-positive organs for HIV-positive kidney and liver candidates.

Organs from donors that fulfill the Public Health Service’s behavioral criteria for being at increased risk for having acquired HBV, HCV, or HIV infection are frequently transplanted following careful case-by-case consideration and after obtaining specific recipient consent [93]. Decision-making by the OPOs and transplant centers regarding the use of organs from these high-risk donors has been greatly facilitated by the now widespread use of nucleic acid testing for those viral pathogens [94].

Potential donors that test positive for the HBV surface antigen, the HBe antigen, or for HBV-DNA are usually precluded from donating. Serologic positivity for the hepatitis B core antigen antibody, however, does not constitute an absolute contraindication to proceed with donation [95]. Acceptable organs from donors with serologic evidence of HBV are usually only transplanted into recipients that have demonstrated immunity against HBV (i.e., HBsAb positivity) [95]. Selected recipients may also receive HBV immunoglobulin or an antiviral agent (e.g., entecavir) or both, beginning at the time of transplant [95]. Ideally, however, all potential organ transplant recipients should have received HBV immunization prior to their pretransplant evaluation.

The use of HCV seropositive donors for selected recipients has become routine [96]. For adequate identification of HCV-positive donors, OPOs routinely perform besides HCV antibody testing and nucleic acid testing for HCV-RNA. HCV-infected livers and kidneys transplanted into HCV-infected recipients do not convey a worse outcome than HCV-negative grafts [96]. The final decision regarding the use of an HCV serology-positive donor must be made on an individual basis by each transplant surgeon. Factors that are taken into account in such circumstances include the likelihood of disease transmission, the recipient’s current medical and serologic status, and the availability of modern drugs for the treatment and eradication of HCV [96].
CMV can also be transmitted by donor tissue, particularly to CMV-seronegative patients. Effective prophylaxis against, and treatment of, CMV disease has become routine because of the availability of highly effective antiviral agents such as ganciclovir and valganciclovir. Positive CMV serologies do therefore not preclude organ donation but have been used to identify high-risk donor–recipient combinations (i.e., CMV-seropositive donor to CMV-seronegative recipient) where enhanced prophylaxis should be used and careful surveillance for CMV disease is important.

However, organ donation is contraindicated if potential donors exhibit or develop active bacterial or fungal sepsis that is unresponsive to adequate source control and antibiotic therapy. Similarly, active tuberculosis is a contraindication to organ donation. Absolute contraindications to donation also include evidence of significant acute viral infections (e.g., viral encephalitis, systemic herpes simplex virus infections, acute viral HAV, HBV, or HCV). For similar reasons, donation should not proceed in patients in whom a definitive etiology for their febrile illness, encephalitis, meningitis, or flaccid paralysis is not ascertainable.

**Transmission of Malignancy.** The risk for transmission of a donor malignancy to a solid organ recipient is low overall [97]. In that regard, appropriate selection of donors with a current or past history of cancer is paramount. If a potential donor has had successful cancer treatment in the past, the transplant surgeon must weigh the small potential risk of transmitting micrometastases against discarding a potentially life-saving organ. In general, patients with a history of malignancy with little propensity to recur after therapy (e.g., small, noninvasive lesions treated by complete surgical excision) are considered as organ donors, particularly if they have remained without evidence of recurrence for more than 5 years. Patients who have experienced invasive cancer in which a substantial risk of late recurrence exists (e.g., breast cancer, malignant melanoma, lung cancer), particularly if a large lesion was initially present and chemotherapy or radiation therapy was used, should not be considered for donation. Similarly, patients with a history of leukemia or lymphoma should not be considered as donors.

Individuals with low-grade skin malignancies such as basal cell carcinoma and most squamous cell carcinomas, and with an in situ carcinoma of the uterine cervix are routinely used as donors.

Patients with tumors of the central nervous system (CNS) can be considered for donation on a case-by-case basis [97,98]. It is important to
ensure that a CNS tumor does not represent a focus of metastatic disease from an extracerebral primary site. Metastases from choriocarcinomas, bronchial or renal malignancies, and malignant melanomas may present as what appears to be a primary brain tumor or may bleed and be mistaken for an intracranial hemorrhage. Previous treatment of a neoplasm, menstrual irregularities after a pregnancy or a spontaneous abortion in women of childbearing age (suggestive of a choriocarcinoma), or evidence of suspicious lesions at other sites in the patient with a purported primary CNS malignancy should preclude organ donation. Donors with primary CNS tumors should not be used if they have undergone radiotherapy, chemotherapy, ventriculoperitoneal or ventriculoatrial shunting, or craniotomies, because these treatments either are associated with high-grade malignancies or create potential pathways for the systemic dissemination of tumor cells [97,98].

Patients with low-grade CNS tumors (grades I to II) should be considered as acceptable donors as long as they were not subjected to any of the aforementioned interventions [18,97,98]. Those with a high-grade (grades III to IV) CNS malignancy and/or one of the aforementioned interventions are at a higher risk for malignancy transmission. In those cases, the transplant surgeon must therefore carefully assess the risk of malignancy transmission versus the risk to the potential recipient of not receiving the organ [18,96,97].

Required Request for Organ Donation and Consent

After the OPO determines the suitability of a potential donor, the next important steps are the brain death examination (when applicable) and the legally required request for organ donation (Table 56.6). Those steps should not involve any of the physicians associated with the transplant team, as this would represent a potential conflict of interest. In 1987, federal required request legislation became effective and has since been adopted by every state in the United States. This requirement has been further strengthened by the CMS’s 1998 Conditions of Participation (vide supra) [75]. Required request laws mandate that the family of a potential organ donor be offered the option of organ donation. The hospital must notify the local OPO of the presence of a potential organ donor. Several studies have shown that consent rates are highest when an OPO coordinator—rather than a member of the patient’s ICU team such as a physician or a nurse—approaches the family about organ donation [11–13,71].

Brain-Dead Donors

For brain-dead donors, it is of utmost importance to ensure that (a) the
family understands and accepts the concept of brain death, including its legal and medical equivalence with death; (b) the request for organ donation not be made at the same time that brain death is explained (unless the family voiced the wish to consider donation earlier during the hospitalization); and (c) the approach and request be made by an OPO representative (rather than a member of the potential donor’s care team). Sufficient time must be given to the next of kin to begin coping with this information and to accept the loss of the family member. Only then, in clear temporal separation from the explanation of death, should the subject of organ donation be broached and an appropriate request be made [11,13]. Also, the family must be informed that, after declaration of brain death and consenting to organ donation, all hospital costs relating to donation will be paid by the OPO.

**DCD Donors**

Families of patients with severe, irreversible brain injuries who do not fulfill the formal criteria of brain death might decide to forgo any further life-sustaining treatment. Only then can the subject of organ donation be broached with the family. As discussed earlier, it is paramount that the approach to the family and the request for organ donation be made by an OPO representative [18,26,27,99,100].

**Consent**

For those individuals that have not expressed in a legally binding form their desire to become an organ donor ("first-person authorization"), the Uniform Anatomical Gift Act of 1968 specifies the legal next-of-kin priority for donors over age 18 years in the following order: (a) spouse, (b) adult son or daughter, (c) either parent, (d) adult brother or sister, and (d) legal guardian [78]. Similarly, the order of priority for donors under age 18 years is as follows: (a) both parents, (b) one parent (if both parents are not available and no wishes to the contrary of the absent parent are known), (c) the custodial parent (if the parents are divorced or legally separated), and (d) the legal guardian (if there are no parents) [71]. The Revised Anatomical Gift Act of 2006 provides stipulations that bar others from overriding a donor’s first-person authorization and empowers minors that apply for a driver’s license to become donors (vide supra) [72,101]. First-person authorization may be provided by signing up with a donor registry (which is now possible online in all 50 States), notation on the driver’s license, a donor card, or documentation of preferences (i) with a primary care provider, (ii) in a durable power of attorney, or (iii) in an advance directive [18]. In part as a result of these now available options, an increasing proportion of patients will have
previously expressed preference for organ donation (i.e., will have provided first-person authorization). In 2015, for instance, 46% of all organ recovery operations were authorized through the donor’s consent that he/she had previously registered with a state donor registry (first-person authorization) [101]. Critical care specialists must be aware that occasionally conflicts may arise from discrepancies between a donor’s wishes expressed in a first-person authorization and the views of their family members or other surrogates. These sensitive situations require resolution through collaboration involving OPO representatives, ICU physicians, hospital representatives, and the patient’s surrogates [18].
PERIOPERATIVE CRITICAL CARE OF THE BRAIN-DEAD ORGAN DONOR

There is an overall lack of randomized, controlled studies that could lead to a more evidence-based approach to the care of these patients. The levels of evidence provided by these studies are generally low. It is therefore important to acknowledge that some of the following recommendations may undergo substantial revision as additional, new evidence emerges (Table 56.7).

Pathophysiology of Brain Death

The majority of our knowledge of the pathophysiologic changes during and after brain death has been derived from experiments performed using animal models. Hemodynamic instability during the phase of impending brain herniation is the result of autonomic dysregulation secondary to the progressive loss of central neurohumoral regulatory control of vital functions. The continuous increase of intracranial pressure with worsening brain ischemia leads to severe systemic hypertension (Cushing’s response) and frequently is associated with tachyarrhythmias. This process is mediated by an increase in sympathetic activity and an excess of circulating catecholamines (“autonomic storm”) [116–118]. A brief period of transient bradycardia associated with the hypertensive response can be seen in the early phase of brain herniation (Cushing’s reflex).

During the phase of increased sympathetic activity, there is evidence that coronary blood flow is significantly impaired, resulting in cardiac microinfarctions. Furthermore, decreased hepatic perfusion due to increased intrahepatic shunting has been demonstrated as a result of the excessive sympathetic activity. Neurogenic pulmonary edema is thought to develop during the autonomic storm phase secondary to the temporary elevation of pulmonary venous pressures over the level of pulmonary arterial and alveolar capillary pressures. This causes massive transudation of fluid from the microvasculature into the alveoli and hemorrhage [116–118]. Within approximately 15 minutes after brain herniation and brain death, catecholamines decrease to below baseline values.

The resting vagal tone is abolished because of destruction of the nucleus ambiguus, eliminating all chronotropic effects of atropine administered after brain death. The total carbon dioxide production after brain death is low, because of the absence of cerebral metabolism and the
presence of hypothermia and decreased muscle tone. The subsequent chronic maintenance phase of brain-dead donors is frequently characterized by hypotension, resulting mainly from complete arterial and venous vasomotor collapse with significant peripheral venous pooling.

Experimental and clinical evidence also shows that brain death leads to activation of proinflammatory and immunoregulatory pathways [106,118–122]. Messenger ribonucleic acid and protein expression within peripheral solid organs of brain-dead donors is significantly increased for cytokines (e.g., interleukin-1β, interleukin-6, tumor necrosis factor-α, interferon gamma, tumor growth factor-β), adhesion molecules (e.g., P- and E-selectin), and vasoconstrictors (e.g., endothelin) [106,118–122]. Importantly, brain death has also been associated with enhanced expression of immunoregulatory molecules such as major histocompatibility complex class I and II proteins. Consistent with these findings, increased immunogenicity and accelerated rejection were noted in kidneys and hearts transplanted from brain-dead rodents [118,119].

### Routine Care and Monitoring

Regular nursing care must be continued after brain death. Frequent turning to prevent decubitus ulcers, skin care, dressing changes, urinary and intravascular catheter care, and catheter site care must be meticulous to minimize the risk of infection. Other indwelling devices should be removed, if possible (e.g., ventriculostomies and ventriculoatrial or ventriculoperitoneal shunts, which may have been inserted in certain patients for monitoring or treating of elevated intracranial pressure). Any urinary and intravascular catheters that may have been inserted under suboptimal, emergent conditions without appropriate aseptic technique at the time of original injury should be replaced. A nasogastric tube should always be inserted for gastric decompression and prevention of aspiration.

Arterial lines should be inserted preferentially into peripheral arteries of the upper extremities because femoral arterial line readings can become inaccurate from surgical manipulation of the abdominal aorta during organ procurement. Similarly, central venous catheters should not be inserted through the femoral vein because dissection and manipulation of the interior vena cava occur during organ procurement. In addition, venous catheters inserted through the femoral vein can cause iliac vein thrombosis. This increases the risk of pulmonary embolization, particularly during surgical venous dissection. Thrombosis can also render the iliac veins unsuitable for use in vascular reconstruction, which may be necessary for some types of abdominal or thoracic organ transplants.
The following parameters must be determined routinely and frequently for all organ donors using various monitoring devices: core temperature (esophageal, rectal, or indwelling bladder catheter temperature probes), heart rate (continuous electrocardiographic monitoring), systemic blood pressure (arterial catheter), central venous blood pressure (subclavian or internal jugular central venous catheter), arterial oxygen saturation (pulse oximetry), and hourly urine output (Foley catheter). Use of a pulmonary artery catheter for measurement of cardiac output, cardiac index, pulmonary arterial and pulmonary arterial occlusion (wedge) pressure, and central venous oximetry is not routinely necessary; their use is typically reserved for selected unstable donors whose volume status is uncertain or who exhibit persistent acidosis with evidence of tissue hypoperfusion. Laboratory parameters also must be checked regularly, including arterial blood gas, serum electrolytes, blood urea nitrogen, creatinine, lactate, and liver enzyme values; total bilirubin; and hemoglobin, hematocrit, platelet count, and coagulation tests. Testing is adapted to the individual clinical situation—e.g., frequent electrolyte determinations if diabetes insipidus has been diagnosed, lactate monitoring in acidic donors, and repeated coagulation profiles in the presence of disseminated intravascular coagulation.

If infection is suspected, blood, urine, sputum, cerebrospinal fluid, and wound drainage cultures must be obtained. Routine surveillance cultures (usually blood and urine cultures) may be required, depending on the protocol of the local OPO and the organ type. Blood cultures should be obtained using peripheral venipuncture, rather than arterial or central venous catheters, to avoid contamination. Prophylactic antibiotics should only be administered immediately before the retrieval procedure. Any source of infection should be identified, characterized from a microbiologic standpoint, and treated with pathogen-specific agents.

**General Management Goals**

The most important overall goal in the management of brain-dead multiple-organ donors is to optimize organ perfusion and tissue oxygen delivery. Organ viability and function after transplantation are closely correlated with adequacy of resuscitation and hemodynamic stability during the organ donor maintenance phase. The events associated with the cause of brain death (e.g., hemorrhagic shock, cardiac arrest) can lead to significant physiologic abnormalities. Head injury preceding brain death is known to induce a hypermetabolic response, equivalent to that observed after a second- or third-degree burn involving approximately 40% of the total body surface area. Significant metabolic stress and impairment of organ perfusion occur during brain herniation, and both events are related to excessive catecholamine
release. Any additional circulatory compromise in the time period afterward potentiates the deleterious consequences of these previous adverse events. Posttransplant organ function can be negatively affected by such episodes of cardiovascular organ dysregulation, particularly in such ischemia-sensitive organs as the heart and liver. For example, even with optimal heart donor management, the recipient often needs inotropic support and may exhibit subendocardial myocyte necrosis on biopsy specimens obtained during the early posttransplant period [21,119]. Anticipating these changes associated with brain death and providing optimal management should they occur during the organ donor maintenance phase, as well as optimizing organ function, are of utmost importance [21]. Parameters associated with adequate tissue perfusion in stable donors in the absence of lactic acidosis are listed in Table 56.7. They include a mean arterial pressure of >60 and/or a systolic blood pressure of 100 to 120 mm Hg, central venous pressure of 6 to 8 mm Hg, oxygen saturation of the arterial blood ≥95%, core temperature ≥35°C, and hemoglobin of 8 to 10 g per dL [19,25], the latter balancing the slightly decreased oxygen transport capacity of the red blood cell mass with the beneficial effects of low viscosity on blood flow. Maintaining adequate hemoglobin concentration is also essential in preparation for organ recovery, in which hemodynamic stability throughout the operation is crucial, especially if blood loss occurs.

Measurement of urine output alone as a means of assessing adequacy of fluid resuscitation is notoriously unreliable in brain-dead donors. A mean arterial pressure >60 mm Hg and the absence of metabolic acidosis (with or without infusion of a small amount of dopamine) with concurrent adequate urine output (at least 1 to 2 mL/kg/h) are usually better indirect indicators of donor stability and sufficient oxygen delivery to organs and tissues (Table 56.8). It is important to remember, however, that the use of vasoconstrictor or inotropic agents is not a substitute for adequate fluid resuscitation. Thus, proper fluid management remains the cornerstone of successful donor management.

The use of vasopressors should be minimized if at all possible because of their splanchnic vasoconstrictive effects. Efforts to elevate blood pressure beyond the normal range can adversely affect outcome and should be avoided: high doses of vasopressors can cause arrhythmias and increase myocardial oxygen consumption, and pulmonary edema after excessive fluid administration can render lungs unsuitable for transplantation. After the lung, the pancreas is the organ most prone to tissue edema. Normal central venous pressure and PEEP help maintain an adequate perfusion gradient across the hepatic microcirculatory bed (i.e., that between the portal vein and hepatic artery on one side and the inferior vena cava and right atrium on the other).

Selective use of pulmonary artery catheterization must be considered in donors who do not respond to routine management and continue to exhibit hypotension or persistent lactic acidosis after adequate volume loading, particularly in those in whom this occurs despite use of moderate doses of dopamine. Determining pulmonary artery and pulmonary artery occlusion pressures, cardiac output and index, pulmonary and systemic vascular resistive indices, oxygen availability and consumption, and other parameters helps to differentiate the cause of instability. In selected patients, echocardiographic assessment of the left ventricular ejection fraction may prove useful. Appropriate therapy can then be administered (e.g., fluid balance correction or PEEP adjustments, additional inotropic support, preload or afterload reduction). Once the hemodynamic instability has resolved, pulmonary artery catheters should be removed to eliminate the inherent risks of infection, induction of arrhythmias, and mechanical endomyocardial damage.
Cardiovascular Support

Hypotension is the most common hemodynamic abnormality seen in brain-dead organ donors. The usual cause is hypovolemia, because of a combination of vasomotor collapse after brain death and the effects of treatment protocols to decrease intracranial pressure, which require minimization of hydration and use of osmotic diuretics (Tables 56.9 and 56.10). After brain death is declared, adequate volume resuscitation of the donor can require several liters of fluid. Until a euvoletic state is achieved, dopamine (greater than 3 µg per kg per minute) can be used temporarily; the dose should be titrated to maintain an adequate systolic blood pressure [18]. Infusion rates greater than 10 µg/kg/min have been associated with increased rates of acute tubular necrosis and decreased renal allograft survival. High infusion rates also lead to decreased perfusion of other organs because of splanchnic vasoconstriction.

### Hypophosphatemia

Causes related to the injury leading to brain death (cardiac tamponade, myocardial contusion)

Myocardial sequelae of autonomic storm

Preexisting cardiac disease

### Drug side effect or overdose

Long-acting β-blocker, calcium channel antagonist, antihypertensive agent

### Hypocalcemia

Transfusions, hypomagnesemia (e.g., secondary to osmotic diuresis), acute renal failure

### TABLE 56.10 Differential Diagnosis of Hypovolemia in the Brain-Dead Organ Donor

- Arterial and venous vasomotor collapse due to loss of central neurohumoral control
- Dehydration (fluid restriction to treat head injury)
- Insufficient resuscitation after the injury leading to brain death (e.g., ongoing hemorrhagic shock with coagulopathy after trauma)
- Polyuria
- Osmotic diuresis (mannitol, hyperglycemia)
- Diabetes insipidus
- Hypothermia
- Administration of other diuretics
- Massive third spacing in response to the original injury
- Decreased intravascular oncotic pressure
Dopamine is also the drug of choice if hemodynamic instability persists after fluid resuscitation and adequate volume loading. Use of isoproterenol and dobutamine should be avoided in this context because of their vasodilatory effects. Drugs with \( \alpha \)-adrenergic agonist effects such as phenylephrine (IV infusion 0.15 to 0.75 \( \mu \)g/kg/min) and norepinephrine (IV infusion up to 0.05 \( \mu \)g/kg/min) should be added only if hypotension persists in the face of euvolementa and titration of the dopamine infusion up to 15 \( \mu \)g/kg/min. \( \alpha \)-Adrenergic agonists can cause severe peripheral vasoconstriction, reduce renal and hepatic perfusion, and may predispose to increased pulmonary capillary permeability. For these reasons, they must be used judiciously. Once these drugs are used, the need for their continued use must be frequently reassessed \([18,25]\). For the majority (>80%) of donors, adequate hemodynamic goals can be achieved with volume resuscitation and low to moderate doses of a single vasopressor agent (dopamine).

Several studies have suggested that administration of catecholamines, and in particular of dopamine, to brain-dead patients may exert a beneficial impact on early kidney graft function and graft survival \([105–107,123]\). Several potential mechanisms have been invoked to explain these observations, including favorable modulatory effects on ischemia–reperfusion and on upregulation of adhesion molecules that results from the inflammatory state induced by brain death \([105–107]\).

Low-dose arginine vasopressin can serve as an alternative first-line or as an additional vasopressor. It enhances vascular sensitivity to catecholamines and causes vasoconstriction through multiple effector pathways; it may thus allow minimizing catecholamine dose and side effects \([111,124,125]\). Effective arginine vasopressin doses for improving hemodynamic stability range from 0.01 to 0.1 International Units per minute (starting dose: 0.01 to 0.04 International Units per minute) given as continuous intravenous infusion \([18,111,124]\). The use of arginine vasopressin in brain-dead organ donors has been associated with improvement of cardiac performance and increased rates of organ recovery \([125]\).

When attempting to determine the etiology of hypotension in an organ donor, underlying cardiac disease (e.g., coronary artery disease, valve defects) and factors related to the cause of brain death (e.g., myocardial infarction, cardiac tamponade, or myocardial contusion) must be included in the differential diagnosis. Electrolyte abnormalities such as
hypophosphatemia, hypocalcemia, hypokalemia, and hypomagnesemia are common in brain-dead organ donors. The presence of these entities must also be considered when hemodynamic instability is encountered, and frequent testing and correction of these significant electrolyte imbalances are important. Hypophosphatemia and hypocalcemia can decrease myocardial contractility and provoke hypotension [126]; hypokalemia and hypomagnesemia can also impair hemodynamics by causing arrhythmias.

For the treatment of arrhythmias or hypertension, medications that possess rapid reversibility and a short half-life are preferred. Hemodynamic instability can be pronounced after brain death, with wide swings between the extremes of hypotension and hypertension, rendering the brain-dead donor more susceptible to cardiovascular drug effects. Hypertension can be treated with short-acting vasodilatory agents (e.g., nitroprusside) or a rapidly reversible β-adrenergic antagonist (e.g., esmolol hydrochloride), because hypertension is usually associated with increased circulating catecholamines. Other drugs, such as calcium channel blockers (e.g., verapamil) or longer-acting β-blockers (e.g., labetalol, propranolol), should be avoided because of their negative inotropic effects and the inability to titrate them precisely.

Bradyarrhythmias during the early phase of brain herniation are part of Cushing's reflex and do not usually require any treatment, unless they are associated with hypotension and asystole. Because of the lack of chronotropic effects by atropine after brain death, use of either isoproterenol or epinephrine is required to treat hemodynamically significant bradyarrhythmias.

Tachyarrhythmias are associated with the increased catecholamine release that occurs during and immediately after brain herniation. Administration of short-acting β-blockers (e.g., esmolol hydrochloride) serves not only to treat arrhythmias but also to mitigate hypertension during the autonomic storm. Use of additional short-acting IV antiarrhythmics (e.g., lidocaine) may become necessary if tachyarrhythmias do not resolve after β-blocker therapy. Calcium channel blockers (e.g., verapamil) must be avoided under these circumstances because of their negative inotropic effects. Cardiac glycosides (e.g., digoxin) also should not be used because they can induce and potentiate bradyarrhythmias and tachyarrhythmias, and they also have splanchnic vasoconstrictive side effects.

Cardiac arrest can occur in up to 25% of all donors during the maintenance phase after brain death and should be treated by routine measures, with the exception that isoproterenol or epinephrine must be substituted for atropine [83,84]. If these measures fail to result in the return of a cardiac rhythm, external (transcutaneous) pacing may be considered. However, the efficacy of external pacing for asystole
associated with brain death is unknown. No intracardiac injections should be given during cardiopulmonary resuscitation because they can render the heart unsuitable for transplantation.

**Respiratory and Acid–Base Maintenance**

Use of endotracheal suctioning is usually minimized during the treatment of cerebral edema to avoid any unnecessary stimulation that would increase intracranial pressure. In contrast, after brain death is declared, vigorous tracheobronchial toilet is important, with frequent suctioning using sterile precautions. Percussion and turning for postural drainage are instituted as well. Even if the lungs are unsuitable for donation, it is important to minimize the risk of atelectasis and infection. Preventing atelectasis facilitates oxygenation and may obviate the need for detrimental high levels of PEEP. Steroids administered to some patients as part of the treatment for increased intracranial pressure predispose to pulmonary infectious complications. The presence of pneumonia can preclude donation of the lungs as well as other organs, depending on its severity and association with systemic sepsis. Routine respiratory care of all donors also includes the use of 5 cm \( H_2O \) PEEP to increase alveolar recruitment and prevent microatelectasis [18,19,25].

The etiology of pulmonary edema in organ donors can be cardiogenic, neurogenic, aspiration induced, a result of trauma or fluid overload, or a combination of these factors. Neurogenic pulmonary edema can preclude lung or combined heart–lung donation, but not donation of other organs (e.g., heart, kidney, liver, pancreas). The treatment for pulmonary edema is supportive and should be directed at maintaining adequate arterial oxygenation without using very high levels of PEEP. Fluids must be administered carefully to maintain organ perfusion while avoiding exacerbation of the edema.

In potential lung donors, the endotracheal tube should not be advanced more than several centimeters into the trachea, to prevent damage to areas that may become part of an anastomosis. A sample of sputum should be obtained for Gram’s stain and cultures to exclude the presence of infection. The samples can be obtained using bronchoscopy, a procedure that is often routinely performed before lung donation.

Traditionally, tidal volumes of 10 to 12 mL per kg and relatively low PEEP target ranges (3 to 5 cm \( H_2O \)) have been recommended. However, there is now evidence that lung-protective ventilatory strategies that have become standard of care for regular ICU patients—i.e., tidal volumes of 6 to 8 mL per kg and PEEP of 8 to 10 cm \( H_2O \)—are also beneficial for the management of the often injured lungs of brain-dead donors [18,25,127,128]. In a randomized trial, the number of transplanted lungs doubled when a lung-protective strategy was pursued [102]. Aggressive
living donor management protocols aimed at improving alveolar recruitment and oxygenation have proven successful with high rates of conversion from unacceptable to acceptable PaO₂/FiO₂ ratios [102]. For potential lung donors, the lowest FiO₂ that is capable of maintaining a PaO₂ of greater than 100 mm Hg should be selected. If oxygenation is insufficient, PEEP should be increased rather than increasing the FiO₂. Very high levels of PEEP may negatively affect cardiac output, which should be carefully monitored in this setting. If hypotension occurs, PEEP should be reduced. Under these circumstances, use of pulmonary artery catheterization should be considered to balance PEEP requirements against those of organ perfusion. In contrast, to correct insufficient arterial oxygenation in nonlung donors, an increase in FiO₂ is preferred over high levels of PEEP [25].

There is no direct evidence stemming from controlled trials that would support a specific fluid management strategy in prospective lung donors. Indirect evidence from studies that involved ICU patients with acute respiratory distress syndrome, as well as prospective lung donors, supports a conservative fluid management approach with prospective donors [102,129]. To date, there is no evidence that such a conservative fluid management approach in donors adversely impacts the function of kidney grafts obtained from the same donor [130]. Excessive use of crystalloid fluids during the initial resuscitation after brain death is declared can render the lungs unsuitable for transplantation. If relatively large amounts of fluid are required for resuscitation and hemodynamic stabilization, colloids (i.e., albumin solutions) or blood transfusions (if the hemoglobin is less than 8 g per dL) should be considered in addition to the infusion of crystalloid solutions [18].

Respiratory alkalosis can develop in brain-dead organ donors secondary to mechanical hyperventilation as part of the treatment protocol for elevated intracranial pressure. After brain death, the arterial pH should be adjusted to normal values because alkalosis has many undesirable side effects, such as increased cardiac output, systemic vasoconstriction, bronchospasm, and a shift to the left of the oxyhemoglobin dissociation curve. The latter decreases oxygen unloading in the tissues and impairs oxygen delivery, thereby diminishing tissue oxygenation and metabolism. Lactic metabolic acidosis is frequent in brain-dead donors; it should be treated by compensation with a slight respiratory alkalosis until the underlying abnormality has been corrected (e.g., dehydration, tissue ischemia). Administration of sodium
bicarbonate should be contemplated only if the increased minute ventilation necessary to induce respiratory alkalosis leads to a decrease in cardiac output. In either situation, the most important aspect of managing metabolic acidosis is to treat the underlying cause. In selected patients this may require pulmonary artery catheterization to assess the adequacy of hydration, cardiac output, and tissue oxygen delivery.

**Renal Function and Fluid and Electrolyte Management**

Maintaining adequate systemic perfusion pressure while minimizing the use of vasopressors contributes to good renal allograft function and reduces the rate of acute tubular necrosis following transplantation. If the urine production is insufficient (e.g., less than 0.5 mL/kg/h) after adequate volume loading, loop diuretics (furosemide, ethacrynic acid, bumetanide) or osmotic diuretics (mannitol) can be considered to initiate diuresis. Nephrotoxic drugs (e.g., aminoglycosides) and agents that may exert adverse effects on renal perfusion (e.g., nonsteroidal anti-inflammatory drugs) are contraindicated. Cephalosporins, monobactams, carbapenems, and quinolones are examples of less nephrotoxic but effective antibiotics that can be used if infection occurs.

Polyuria in brain-dead donors is a frequent finding. It can be due to diabetes insipidus, osmotic diuresis (induced by mannitol administered to decrease elevated intracranial pressures or hyperglycemia), physiologic diuresis due to previous massive fluid administration during resuscitation after the original injury with return of third-space fluid into the intravascular space, or hypothermia. Diabetes insipidus often heralds brain death in head-injured patients. It is the most frequent cause of polyuria during the organ donor maintenance phase. Found in up to 80% of all brain-dead bodies [81], it is related to insufficient blood levels of antidiuretic hormone (vasopressin), resulting in the production of large quantities of dilute urine.

Diabetes insipidus should be suspected when urine volumes exceed 300 mL per hour (or 7 mL/kg/h) in conjunction with hypernatremia (serum sodium greater than 150 mEq per dL), elevated serum osmolality (greater than 310 mOsm per L) and a low urinary sodium concentration. In addition to hypernatremia, other electrolyte abnormalities frequently observed during diabetes insipidus include hypokalemia, hypocalcemia, and hypomagnesemia. The appropriate replacement of these electrolyte losses can be guided by urinary electrolyte determinations, which easily allow calculation of the amount of the electrolyte to be replaced. Because diabetes insipidus is so common, mannitol administration should be discontinued after brain death is declared. Other supportive care of patients with diabetes insipidus includes replacing urine output milliliter for milliliter with free water (e.g., 5% solution of dextrose in water IV).
Once urine output due to diabetes insipidus exceeds 300 mL per hour, desmopressin (desamino-8-D-arginine vasopressin), a synthetic analog of vasopressin (or arginine vasopressin), should be administered. Desmopressin has a long duration of action (6 to 20 hours) and a high antidiuretic-to-pressor ratio, without any undesirable splanchnic vasoconstrictive effects that can occur with administration of normal- and high-dose arginine vasopressin [18,25,131]. For example, doses of 1 to 2 μg desmopressin are administered intravenously every 8 to 12 hours to achieve a urine output less than 300 mL per hour [18,25,131]. Desmopressin can also be effectively administered subcutaneously, intramuscularly, and intranasally. Alternatively, in donors with diabetes insipidus that are also hypotensive due to a low systemic vascular resistance (SVR), an arginine vasopressin IV infusion can be started at 0.5 International Units per hour and titrated up to 6 International Units per hour, targeting a urine output of 0.5 to 3 mL/kg/h and a serum sodium of 135 to 145 mEq per L [18,25]. Compared to desmopressin, arginine vasopressin is easily titrated and adds beneficial hemodynamic effects.

The choice of the resuscitation fluid depends on the clinical circumstances and the donor’s electrolyte, osmolar, and acid–base state. Generally, for intravascular volume replacement, an isotonic crystalloid is preferred (i.e., 0.9% saline solution [in hypoosmolar patients] or lactated Ringer’s solution [in the setting of hyperchloremic metabolic acidosis]). For correction of hypernatremia in euvelemic or near-euvolemic patients, hypotonic fluids (e.g., D5W or 0.45% saline solution) can be administered (e.g., during the initial resuscitation phase after brain death is declared) [18]. For intravascular volume expansion to address acute hypotension, albumin 5% is the preferred colloid. Use of low- or high-molecular-weight hydroxethyl starch (HES) is contraindicated as it is associated with acute kidney injury and coagulopathy because it is trapped within the hepatic reticuloendothelial system. Consistent with these concerns, HES use in donors was shown to result in higher delayed kidney graft function and failure rates [132].

Subsequently, maintenance fluid should consist of 5% dextrose in 0.45% sodium chloride with 20 mEq potassium added to each liter, administered at a rate of 2 mL/kg/h during the maintenance phase if urine output is adequate (greater than 1 to 2 mL/kg/h). If the urine output is greater than 2 mL/kg/h, IV fluids should be administered at a rate equal to the urine output during the previous hour (IV intake = urine output). If the serum sodium concentration exceeds 150 mEq per dL, the maintenance fluid should consist of 5% dextrose solution with 20 mEq potassium added to each liter. Should the hourly fluid administration rate exceed 500 mL per hour, the dextrose concentration of the maintenance fluid should be decreased to 1% to avoid excessive hyperglycemia.
maintenance fluids administered to brain-dead organ donors should contain glucose, which is important to maintain intrahepatic glycogen stores that appear to be associated with normal liver allograft function in the early posttransplant period. In hypernatremic patients, the sodium content of certain IV fluids and plasma expanders (e.g., albumin solutions) must also be taken into consideration.

Endocrine Therapy

According to prior studies, pituitary hormone blood levels do not uniformly decrease after brain death. Diabetes insipidus develops in approximately 80% of brain-dead donors as a result of low or absent blood levels of vasopressin [80]. These findings are a direct consequence of brain death, which abolishes vasopressin production in the hypothalamic nuclei (supraoptic and paraventricular nuclei) and vasopressin storage and release in the posterior pituitary. In contrast, near-normal levels of anterior pituitary hormones, such as thyroid-stimulating hormone, adrenocorticotropic hormone, and growth hormone, have been documented after brain death in some studies [133–136]. Their persistence is probably due to the preservation of small subcapsular areas in the anterior pituitary, the blood supply of which is derived from small branches of the inferior hypophyseal artery. The latter arises from the extradural internal carotid artery, which is relatively protected from increases in intracranial pressure [137]. Clinical evidence, however, suggests deficient adrenal cortisol secretion after dynamic stimulation in brain-dead donors, irrespective of the level of pituitary dysfunction [138].

The principle of pharmacologic replacement therapy for deficient posterior pituitary vasopressin after brain death is well established [18,19,25,111]. A retrospective UNOS database analysis demonstrated a significant association between desmopressin use in donors and organ yield (Table 56.7) [110]. Low-dose vasopressin has been shown to exert beneficial hemodynamic effect in brain-dead donors (Table 56.7) [111,125].

In contrast, controversy still exists regarding the benefits of supplementation with triiodothyronine [T3] and thyroxine [T4], which are synthesized under anterior pituitary control (Table 56.7) [18,19,25,110,112,114,139–148]. Initially, the presence of low T3 blood levels was demonstrated after brain death in animal experiments [149]. Administration of exogenous T3 to donor animals improved a variety of metabolic parameters before and after organ preservation [150–152], as
well as organ function after transplantation [153]. These findings suggested possibly positive effects of T3 also in human donors. A limited number of uncontrolled clinical trials suggested favorable influences of donor pretreatment with thyroid hormone on hemodynamic and metabolic parameters during the donor maintenance phase [84,154,155] and on outcome after heart transplantation [156–158]. But a number of other investigators failed to observe a significant benefit of thyroid hormone administration on biochemical and hemodynamic donor parameters and on posttransplant outcomes (Table 56.7) [112,113,159,160].

The latter outcomes could be explained at least in part by the findings of some studies which have suggested that the low T3 levels in human donors do not correlate with the presence of hemodynamic stability [161,162] or outcome after transplantation [163–166] to begin with. The typical thyroidal hormonal pattern after brain death consists of decreased T3, normal or decreased thyroxine, and normal thyroid-stimulating hormone. This pattern is not consistent with acute insufficiency of the hypothalamic–pituitary–thyroid axis or clinically overt hypothyroidism, but is similar to changes (sick euthyroid syndrome) observed in other groups of critically ill individuals. Thyroid hormone administration to such patients may not only be ineffective but may theoretically even be detrimental in some cases [145,146]. In summary, there is no conclusive evidence to date that supplementation of organ donors with thyroid hormone alone yields a significant clinical benefit. As per a consensus recommendation by leading North American critical care medicine societies and the U.S. Association of OPOs, thyroid hormone replacement therapy—either alone or as part of a combination protocol—should at present be considered for hemodynamically unstable donors with abnormal (<45%) left ventricular ejection fraction (vide infra for thyroid hormone dosing guidelines) [18].

By contrast, evidence for the potential benefits of routine administration of corticosteroids alone has emerged [18,108–110]. Normal human serum adrenocorticotropic hormone and cortisol levels have been demonstrated after brain death in some studies, whereas others have observed dysfunction of the hypothalamic–pituitary–adrenal axis in patients with traumatic brain injury [133–136]. Clinically, however, administration of high-dose steroids was noted to stabilize and improve lung function, leading to higher probability of lung recovery from brain-dead patients that had previously not been considered for lung donation, to increase organ yield, and to lead to improved outcomes after liver transplantation [19,108–110,167,168].

Published retrospective evidence suggests that institution of empiric donor management protocols that incorporate combination treatment with arginine vasopressin, high-dose corticosteroids, thyroid hormone,
and insulin may stabilize and improve cardiac function in brain-dead donors and may result in increased probability of kidney, heart, liver, lung, and pancreas recovery and transplantation and may improve posttransplant outcomes (Table 56.7) [114,139,140,142–144]. These and other findings have served as the basis for recommendations from a national U.S. consensus conference held in 2001 that include: T3: 4 μg bolus, 3 μg per hour continuous infusion; arginine vasopressin: IU bolus, 0.5 to 4.0 International Units per hour continuous infusion (titrate SVR to 800 to 1,200 using a pulmonary artery catheter); methylprednisolone 15 mg per kg intravenous bolus, repeat every 24 hours; and insulin continuous intravenous infusion at a minimum rate of 1 unit per hour (titrate blood glucose to 120 to 180 mg per dL) [20,21]. However, given the uncertainty regarding potentially adverse side effects and the absence of high-level evidence, large prospective randomized trials are necessary before routine administration of hormonal combination therapy can be recommended for all donors—particularly because, for example, excellent lung procurement rates from marginal donors and good posttransplant outcomes have also been described in the current era without hormonal supplementation (Table 56.7) [169]. Moreover, the optimal dose and combination, as well as the contribution of each individual hormone to the observed overall outcome remain yet to be studied and elucidated. For now, it appears prudent to reserve routine combination hormone replacement therapy for hemodynamically unstable donors that require substantial catecholamine doses (e.g., dopamine >10 μg/kg/min) or have an ejection fraction of less than 45% [18,20,21,25].

Although brain death is not associated with primary pancreatic endocrine dysfunction, hyperglycemia is frequent in brain-dead donors. Hyperglycemia can be caused by increased catecholamine release, altered carbohydrate metabolism, steroid administration for treatment of cerebral edema, infusion of large amounts of dextrose-containing IV fluids, or peripheral insulin resistance. Treating hyperglycemia in brain-dead donors appears to be important with regard to pancreatic islet cell function. Experimental evidence suggests that high glucose levels may produce transient or irreversible damage to beta cells in the pancreatic islets, in vitro and in vivo [170,171]. This glucose toxicity was attenuated during in vivo experiments by correcting hyperglycemia [172]. Clinical studies in pancreas transplant recipients have demonstrated that donor hyperglycemia is a risk factor for decreased graft survival [88]. It was not established in these studies, however, whether donor hyperglycemia was indicative of marginal or insufficient beta-cell mass or whether impaired pancreatic graft function was related to islet cell dysfunction as a result of hyperglycemia.
Hyperglycemia in and of itself is known to cause insulin resistance [173]. Studies in brain-dead donors have suggested that a state of hyperinsulinemia coupled with peripheral insulin resistance exists, as evidenced by elevated C-peptide–glucose molar ratios [174]. For all the above reasons, it is prudent to maintain blood glucose levels in donors between 120 and 180 mg per dL [175]. Insulin should be administered as needed according to the blood glucose values to mitigate any potential adverse effects of hyperglycemia on pancreatic islets, which could impair glucose homeostasis after transplantation [175]. If hyperglycemia persists despite initial bolus insulin therapy, continuous IV insulin infusion should be instituted to facilitate titration of glucose levels. As in many other critical care patients, good glycemic control is also good standard practice for brain-dead donors, because it acts to prevent ketoacidosis and osmotic diuresis, both of which can be significant problems in the management of brain-dead donors, and because it may contribute to improved overall organ recovery and transplantation rates [176].

**Hypothermia**

After brain death, the body becomes poikilothermic because of the loss of thalamic and hypothalamic central temperature control mechanisms, and hypothermia usually ensues [177]. Systemic vasodilation causes additional heat loss. Hypothermia can be aggravated by administering room-temperature IV fluids and cold blood products. Adverse effects of significant hypothermia include decreased myocardial contractility, hypotension, cardiac arrhythmias, cardiac arrest, hepatic and renal dysfunction, and acidosis and coagulopathy [178–180]. Therefore, donor core temperature should be maintained at or above 35°C. It is usually sufficient to use humidified, heated ventilator gases; warmed IV fluids and blood products; and warming blankets to achieve rewarming and to maintain an adequate body temperature. Rewarming with peritoneal dialysis or bladder irrigations generally should not be performed in organ donors.

In a randomized trial, a mildly hypothermic target temperature range of 34°C to 35°C in brain-dead patients was associated with significantly decreased delayed graft function rates in the recipients of kidneys from these donors [104]. The effect of mild hypothermia on extrarenal donor organs, however, remains unknown for now. It is therefore premature to recommend a mildly hypothermic core temperature target range for all brain-dead donors.

**Coagulation System**
Coagulopathy and disseminated intravascular coagulation are common findings in brain-dead donors, particularly after head injuries. Pathologic activation of the coagulation cascade occurs when brain tissue, which is very rich in tissue thromboplastin, comes in contact with blood after trauma. Massive blood transfusions can produce dilutional thrombocytopenia, and subsequent ongoing hemorrhage, hypothermia, and acidosis are all able to trigger or further aggravate coagulopathy. Clinical findings can include pathologic bleeding, abnormal prothrombin time, thrombocytopenia, hypofibrinogenemia, and increased levels of fibrin/fibrinogen degradation products. Treatment of coagulopathy entails use of blood components such as platelets, fresh-frozen plasma, or cryoprecipitate and correction of the underlying pathophysiology (e.g., hypothermia, acidosis, surgical hemorrhage). ε-Aminocaproic acid and tranexamic acid should not be used because of their potential for inducing microvascular thrombosis, thereby rendering organs potentially unsuitable for transplantation [181].

Other Aspects

Brain death may also adversely affect the donor’s nutritional status. Experimental studies have suggested a hypercatabolic state and decreased hepatic intracellular ATP levels [182]. Moreover, a suboptimal organ energy and redox status along with the inflammatory changes that result from the chemokine and cytokine release associated with brain death may exert a deleterious influence on the magnitude of, and recovery from, ischemia–reperfusion injury and on posttransplant organ function in the recipient. Appropriate nutritional support of the donor may be able to prevent depletion of micro- and macronutrients and may attenuate oxidative stress and ischemia–reperfusion injury. However, currently, there are no clinical data available that would directly support routine nutritional supplementation of brain-dead donors. For potential small bowel donors, it may be justified to continue any already instituted tube feedings given the beneficial effects of the latter for the maintenance of the intestinal mucosa’s integrity [18,34].

Various pharmacologic donor pretreatment protocols to optimize donor and transplant outcomes have been reported. The potential clinical effects of administration of catecholamines, vasopressin (or its analog desmopressin), and of steroids on both donor and posttransplant outcomes have already been discussed in detail (Table 56.7). In other studies, verapamil mitigated the adverse impact of elevated cytosolic calcium levels on renal allograft function [183] after donor hemodynamic instability. Finally, donor pretreatment with immunosuppressants (other than steroids) may have a favorable impact by preventing upregulation of proinflammatory pathways and increased expression of major
histocompatibility complex molecules that have been demonstrated to occur after brain death [120–122]. The latter pretreatment modalities, however, must be investigated more extensively before they can be routinely applied.

Multiple-Organ Donor Operation

After consent is obtained, the OPO schedules and organizes the organ recovery operation. Often, several surgical teams from different locations participate; their transportation and the preparation of the recipients in the various hospitals must be meticulously coordinated. After certification of death according to the state laws occurs, the brain-dead donor is brought to the operating room. Full cardiovascular and ventilatory support is maintained throughout the operation, until the organs are flushed and cooled. The principles of brain-dead donor management should be reviewed with the anesthesiologist, unless he or she is familiar with the specific clinical aspects of cardiovascular and ventilatory support for brain-dead organ donors. Hemodynamic stability must be maintained during the surgical organ retrieval, which is the equivalent of a combined major abdominal and thoracic operation and can last up to several hours. Transient tachycardia and hypertension may occur while the surgical incision is being made; they most likely reflect spinal reflexes causing vasoconstrictive responses and adrenal stimulation. Subsequently, consideration must be given to the increased heat loss caused by the wide abdominal and thoracic incisions and the duration of the surgery. Neuromuscular blocking agents (e.g., vecuronium, cisatracurium, or rocuronium) should be used to inhibit reflex muscular contractions [82]. Tubocurarine (which is not available anymore in many countries) should also not be used in brain-dead donors because of its association with hypotension as a consequence of histamine release and ganglionic blockade. Maintenance fluid administration throughout the operation must take into account the significant intraoperative fluid losses resulting from extensive dissection with evaporation and blood loss, transection of lymphatic channels, and massive third-space fluid loss.

All organs to be recovered are completely mobilized, and their vascular pedicles are dissected free. At the end of the operation, systemic heparinization occurs and cannulas are inserted (depending on the organs to be procured) into the abdominal aorta, inferior vena cava, portal vein, aortic arch, and pulmonary artery. Only then is circulation
and respiratory support terminated. The organs are flushed in situ with preservation solution to remove blood and to cool the organs to a temperature of 4°C to 7°C. Simultaneously, topical external cooling is provided by the application of sterile ice slush. The organs are then individually removed, by dividing the remaining attachments and vascular pedicles, and then packaged [47]. Storage in preservation solution at 4°C to 7°C in a cooler surrounded by crushed ice allows maximal preservation times of 4 to 6 hours for heart and lungs, approximately 30 hours for livers and pancreata, and about 40 hours for kidneys. These preservation constraints are taken into consideration as organs are allocated. Critical care of the donor ends when controlled cardiac arrest occurs at the completion of the surgical organ recovery. This finality is ephemeral, however, because it results in the start of new lives for the recipients after a successful organ transplant.
PERIOPERATIVE CRITICAL CARE OF THE DCD ORGAN DONOR

Preoperative Care of the Potential DCD Donor (Prior to Obtaining Consent for Organ Donation)

Therapy in those patients must remain primarily aimed at treating the underlying pathology (e.g., head trauma, cerebrovascular accident). Any premature (i.e., prior to the family having made the decision to withdraw care and prior to obtaining consent) change of therapeutic objectives would be unethical and may ultimately lead to overall lower consent rates, thereby further exacerbating the current donor organ shortage [26,27,97].

Preoperative Care of the Actual DCD Donor (After Having Obtained Consent for Organ Donation)

Once consent to proceed with organ donation has been obtained, the focus switches from cerebral protection to preservation of organ function and optimization of peripheral oxygen delivery [26,27,97]. Maintenance therapy endpoints in DCD donors are identical to those that apply for brain-dead organ donors (Table 56.8). Because DCD donors do not exhibit the same pathophysiologic characteristics as brain-dead donors, general management principles for DCD donors are more akin to those that apply to non–brain-dead patients in the ICU that are described elsewhere in this book. Organ-specific considerations (e.g., use of catecholamines) are the same as those described earlier for brain-dead donors.

Preterminal and Intraoperative Care of DCD Donors

Maintenance therapy as outlined earlier is continued until technologic support is withdrawn and the patient is extubated (either in the ICU or in the operating room). Any additional premortem interventions (e.g., surgical: insertion of femoral cannulas in preparation of organ recovery; pharmacologic: administration of intravenous heparin, opioids, and phentolamine) must occur in strict accordance with local OPO/hospital DCD protocols and policies [26,27,97,184,185]. Death is then pronounced by a physician (usually the patient’s intensive care physician) not belonging to the organ recovery and transplant team, according to
criteria that are specified by the local OPO/hospital DCD protocol. Next, after an additional 2- to 5-minute waiting time, surgical organ recovery begins [26,184,185]. For DCD donors, the use of a rapid procurement technique is mandatory in order to minimize warm ischemia time, particularly when highly ischemia-sensitive organs such as the liver, pancreas, or lungs are to be recovered as well [48].

Disposition of the patient, if death does not occur within the specified waiting time (which typically ranges between 30 and 90 minutes) after withdrawal of support, is determined by the local protocol (e.g., return of patient to a non–intensive care hospital floor for comfort care only). This aspect is particularly important because as a result of the global efforts to maximize DCD, an increase in the numbers of “unsuccessful” withdrawals of support is to be expected (and must be acceptable to the providers that care for these patients during their terminal hospital admission).

INTRODUCTION

Kidney transplantation is more than a life-enhancing endeavor; it is life-saving. A recent study estimated that more than 1.3 million life-years have been saved from over 300,000 kidney transplantations in the United States over the past 25 years [1]. Other studies have calculated a projected 10-year survival benefit for an average cadaveric kidney transplantation [2]. More than just survival benefit, a successful transplantation can free a patient from the demands of dialysis and provide a higher quality of life at a fraction of the overall cost compared to those not transplanted [3]. In the United States, the cumulative 1-year graft survival rate was 91.3% for deceased donor recipients and 96.4% for living donor recipients; and 5-year graft survival rate of 68.9% for deceased donor recipients and 81.5% for living donor recipients. The half-life graft survival is projected for deceased donor recipients to be 10 years; for living-related donor recipients, almost 18 years [4,5].

Enthusiasm for kidney transplantation is undoubtedly fueled by these promising outcomes; however, a donor shortage crisis remains. Over 100,000 patients are waitlisted for kidney transplantation on an ever-growing list. This waitlist is in the context of just 17,000 annual kidney transplants in the United States. In 2008, the median waiting time was 4.2 years, increased from 2.7 years in 1998 [6]. These protracted waiting times subject our patients to a great deal of harm from the ill effects of uremia and dialysis. Critical care providers, therefore, are facing a cohort of patients awaiting kidney transplantation who are sick and getting sicker. This chapter discusses the salient points of critical care to optimize outcomes after kidney transplantation.
PRETRANSPLANT EVALUATION

In addition to the aforementioned ill effects of prolonged dialysis, kidney transplant candidates are commonly plagued with significant comorbidities, often the etiology of their renal failure; including hypertension, diabetes, and cardiovascular disease. It is therefore imperative that the pretransplant evaluation should be exhaustive (covering cardiovascular, gastrointestinal, pulmonary, neurologic, genitourinary, and infection disease concerns). The goal is not only that the patient should survive the operation and hospitalization, but also survive in the long term so that there is a realization of the potential graft life of the donor allograft.

The cardiovascular examination is the most important because cardiac events constitute the most common cause of death in the perioperative and postoperative periods [7]. Ironically, our preoperative screening with noninvasive cardiac stress testing is notoriously unreliable. In a meta-analysis, the sensitivity of the pretransplant cardiac perfusion study for myocardial infarction was only 0.7; and for cardiac death, only 0.8 [8,9]. The onus remains on the transplant clinician to be highly suspicious of potential cardiac morbidity, even in younger patients with prolonged renal failure. Abnormalities detected by stress testing require coronary angiography to investigate the need for coronary stenting or even coronary artery bypass. It may also be reasonable to perform coronary angiography on high-risk patients with significant comorbidities or a pronounced history of cardiac problems with unremarkable stress testing.

Carotid duplex ultrasound should be used to screen candidates with a history of stroke or transient ischemic attacks (TIAs) for critical carotid stenosis. Pulmonary function testing should be used to screen patients with any history of pulmonary disease including COPD and asthma. Since hepatitis C exposure is so common in the hemodialysis (HD) population, screening with liver function test and hepatitis C (HCV) testing should be conducted [10]. Abnormal results should prompt consultation with a hepatologist and further testing. Since gastrointestinal diseases are more common in patients with end-stage renal disease, any upper GI symptoms should elicit an EGD. Screening with colonoscopy is mandatory for candidates older than 50 years. Recurrent urinary tract infections or bladder dysfunction requires urodynamic testing and
urology consultation. Candidates with any history of hypercoagulability should undergo a complete thrombophilia evaluation. Abnormal results require hematology consultation and a plan for therapeutic measures in the perioperative period.
PERIOPERATIVE CARE

Pretransplant Preparation

Careful preparation in the days and hours before transplantation is essential to achieve ideal outcomes. For HD-dependent patients, a routine HD session on the day prior to transplant would be acceptable. If this is not the case, HD should be performed in the hours prior to surgery. An electrolyte panel should be checked within hours of anesthetic induction. Dialysis catheter sites should be inspected for infection for patients on HD. Peritoneal fluid should be obtained for culture and Gram stain for patients on peritoneal dialysis (PD). In addition to electrolyte screening, a complete history and physical examination, electrocardiogram, chest X-ray, and laboratory examination should be performed just prior to the operation to uncover any possible health derangements since the last physician visit. The history should include a comprehensive review of the medication list. Anticoagulants should be held including warfarin and Plavix. β-blockade should be continued through the perioperative period.

Intraoperative Care

The degree of invasive monitoring during the operation should reflect the extent of the recipient’s comorbidities. Central venous catheters are commonly introduced to guide intraoperative and postoperative fluid management. This access is also essential to administer the most commonly used induction agent, thymoglobulin. Continuous arterial blood pressure monitoring is also quite common and facilitates blood pressure management during the case. It can also be instrumental to optimize the recipient’s blood pressure just prior to reperfusion. Pulmonary artery pressure monitoring is used much more selectively. It is justified when recipients have significant cardiac dysfunction, valvular abnormalities, or significant pulmonary artery hypertension. A 20-F three-way Foley catheter is useful to inflate the bladder with saline that greatly facilitates the ureteroneocystostomy. After completion of this anastomosis, urine output is checked frequently to guide fluid resuscitation. Compression stockings and sequential compression devices provide deep venous thrombosis prophylaxis.

Optimizing the immediate perfusion of the allograft is vital to maximize graft function. This is achieved by maintaining adequate intravascular volume with a central venous pressure (CVP) between 10 and 15 mm Hg. The goal is a systolic blood pressure of greater than 120
mm Hg at the time of reperfusion. If this is not achieved with appropriate volume loading, then low-dose dopamine can be used. Other vasopressors should be avoided since they can effectively reduce perfusion of the allograft. Another strategy, shown to decrease the incidence of acute tubular necrosis (ATN), is to give Mannitol (1 g per kg) with furosemide prior to reperfusion to increase urine flow [11]. Optimizing the chance of immediate graft function requires careful communication and coordination between anesthesia and surgical teams. Immediate graft function is important because both ATN and delayed graft function (DGF) have been found to increase patient mortality [12].

Immediate Postoperative Care

Recipients with significant comorbidities may require admission to the intensive care unit (ICU) for optimal monitoring and fluid resuscitation. Most patients, however, can receive appropriate care on a solid-organ transplant ward provided there is mechanism for proper fluid resuscitation. This can be challenging, with the voluminous urine output often encountered with immediate graft function. The basis of the resuscitation is the equivalent replacement of urine output milliliter for milliliter, which is measured hourly. A 5% dextrose and 0.45 normal saline solution should be administered; potassium replacement may also be necessary, but should not exceed 0.3 mEq/kg/h. For recipients with cardiac dysfunction, replacement should be lower at 0.5 mL of replacements for 1 mL of urine. After 24 hours, the fluid replacements are converted to a continuous rate between 100 and 150 mL per hour based on the recipient weight and kidney function.

Serial blood counts, coagulation profiles, and chemistries should be obtained in the postoperative period. Electrolyte abnormalities, especially hyperkalemia, hypokalemia, hypomagnesaemia, and hypocalcaemia are common and should be corrected. Serial troponins should be obtained to exclude myocardial ischemia with select recipients with significant cardiac comorbidity. Chest X-ray and electrocardiograms are obtained in the immediate postoperative period.

ICU monitoring can become necessary at any time if complications should develop. Kidney transplant recipients are prone to complications owing to their significant comorbidities, intense immunosuppression, and variable graft function. It is estimated that between 15% and 30% of high-risk transplant candidates will require specific critical care.
Critical Evaluation of Dysfunctional Grafts

Immediate graft function is reliably indicated with the combination of brisk diuresis (>100 to 200 mL per hour) and a consistent downward trend in serum creatinine. Diuresis on its own may be a result of the urine produced by the recipient’s native kidneys or the residual effect of diuretics infused during the operation. DGF is affected by a multitude of factors including prolonged cold ischemia time, advanced donor age, and donor diabetes among a host of others. While rare with living donor transplants, the incidence of DGF in cadaveric donors is about 25%. Most allografts with DGF start to recover by 10 days. Doppler ultrasound plays a vital role in the surveillance of the allograft in DGF or for allografts with immediate function that abruptly changes. Intensivists must be aware that ultrasound can rule out surgical complications that require immediate therapeutic maneuvers to salvage the graft including clearing of arterial or venous thromboses.

Medical Complications Leading to Early Graft Dysfunction

Acute Tubular Necrosis

There are a variety of medical and surgical causes of impaired kidney function after transplantation. The most common culprit is ATN, which fortunately has the best prognosis. It is estimated that up to 35% of deceased donor recipients have ATN, but is rare in living donor recipients. About 95% of recipients with ATN will eventually recover kidney function, in some cases requiring HD for several weeks. The causes of ATN are many and often multifactorial, with the most common cause being prolonged ischemia times. Other indicators of poor donor quality such as advanced donor age and donor diabetes mellitus (DM) are also common culprits. Donor and recipient instability requiring the use of vasopressors also contribute. There is a host of immunologic risk factors that are factors causing ATN, as well, including poor human leukocyte antigen (HLA) matching and donor-specific antibodies. Although most recipients with ATN recover, ATN has a detrimental
effect on graft function and graft survival. ATN leads to a higher incidence of rejection and chronic allograft nephropathy \[15\].

ATN is a diagnosis of exclusion. Most importantly, surgical complications need to be ruled out, most notably, thrombosis with a Doppler ultrasound. Next, the clinician is obligated to rule out urologic complications and rejection.

**Acute Rejection**

Acute rejection in kidney transplantation is of great significance, but a comprehensive review is beyond the scope of this chapter. There are two types of acute rejection, cellular rejection and antibody-mediated rejection; both can diminish graft function and survival \[16\]. At present, this diagnosis is secured with a kidney biopsy, although there are efforts underway for noninvasive diagnostics. After vascular thrombosis and urologic complications are ruled out, the next step is often a biopsy to rule out rejection. Acute cellular rejection, which is a lymphocytic attack against donor tissue, is most often treated with a course of steroids or thymoglobulin. Antibody-mediated rejection that may occur in conjunction with acute cellular rejection or occur on its own is most often treated with a course of plasmapheresis and IVIG and in some cases Rituximab. In antibody-mediated rejection, preformed or de novo alloantibodies target capillary endothelium and by activating the complement system can result in rapid destruction of the allograft.

**Recurrence of Kidney Disease**

Most types of kidney diseases rarely recur in the acute setting; the exception, however, are focal segmental glomerulosclerosis (FSGS) and hemolytic uremic syndrome (HUS) that can cause early and profound graft dysfunction. Nephrotic range proteinuria (i.e., >3.5 g per day) in a transplant recipient with known FSGS should prompt an immediate biopsy. Diffuse foot process effacement on biopsy is diagnostic. Early graft dysfunction with laboratory evidence of microvascular trauma including low haptoglobin levels, elevated lactate dehydrogenase levels, and the presence of schistocytes on blood smear should elicit suspicion of HUS and prompt a biopsy as well. It may be recurrent or de novo, with the patient’s calcineurin inhibitor being a well-known causative agent \[17\].

**Surgical Complications Leading to Early Graft Dysfunction**

*Hemorrhage* after surgery is always a possibility but is rare in kidney
transplantation because the surgical field is confined to the retroperitoneal space, so bleeding usually tamponades. Reexploration is uncommon. Bleeding is suspected if the patient is tachycardic, hypotensive, oliguric, and requiring blood transfusions. Subscapular bleeding in the allograft is an entirely different matter, as it can lead to compression and quick deterioration of allograft function. If this is recognized on Doppler ultrasound with evidence of compression, immediate reexploration is imperative to release the hematoma.

Arterial thrombosis is a devastating complication in kidney transplantation, as the renal arteries are end arteries without collateralization. Therefore, arterial thrombosis almost invariably results in graft loss; however, fortunately it is rare (0.7% to 5%) [18]. As mentioned earlier in the chapter, impaired graft function or a sudden change in urine output should elicit a Doppler ultrasound, which is usually diagnostic when thrombosis is present. If discovered early, within hours, graft salvage is possible although most cases result in irreparable damage necessitating transplant nephrectomy. Unidentified intimal flaps, allograft damage in the procurement, donor–recipient size discrepancy, hypotension, and technical difficulty with multiple arteries in the donor or diseased iliac vessels in the recipient are all identified causative factors [18].

Renal vein thrombosis is equally devastating and uncommon and occurs in 0.3% to 4.2% of recipients. It is most often diagnosed within a few days after the transplant and is characterized by sudden onset of pain and graft swelling, hematuria, and, in the case of iliofemoral thrombosis, an edematous leg. In addition to the vein thrombosis, the Doppler ultrasound often shows reversal of the diastolic flow in the arterial system and an enlarged kidney possibly surrounded by hematoma. Urgent allograft nephrectomy is necessary in complete thrombosis to prevent kidney rupture and devastating hemorrhage. Partial thrombosis is an indication for urgent surgical thrombectomy or thrombolytic therapy. It is most often caused by kinking of the anastomosis, intimal injury during organ procurement, pressure on the vein secondary to a fluid collection (i.e., lymphocele, urinoma, or hematoma), compartment syndrome, and extension of an iliofemoral thrombosis [19].

Other vascular complications include aneurysms and renal artery stenosis. Aneurysms can be anastomotic (pseudoaneurysm) or infected (mycotic) and require surgical repair. Recipients with renal artery stenosis require percutaneous balloon dilation, or if unsuccessful, surgical repair.

Urologic complications are much more common than vascular complications, but if addressed systematically, rarely threaten the viability of the allograft. Urologic complications, including hematuria, urine leaks, and ureteral stenosis, range from 5% to 14% [20].
Hematuria is not uncommon from operating on the distal ureter and bladder and often resolves within 24 hours; however, clot formation leading to obstructive uropathy can occur, especially with poor initial urine flow. Close monitoring of the urine output is necessary and any changes can indicate obstruction. Large clots can cause suprapubic pain and bladder spasms. Catheter irrigation can often remedy the situation. If unsuccessful, manual evacuation using a 20-F Six-eye Foley catheter can be used. Occasionally, hematuria can be caused by posttransplant biopsies with blot clots forming in the renal pelvis. In these situations, a percutaneously placed nephrostomy tube may be necessary.

Urine leaks are caused by technical error with the ureteroneocystostomy, presenting in the first few postoperative days, or from ureteral ischemia and necrosis, presenting in the first few weeks. The presentation can be quite varied, including wound drainage, persistent tenderness, fevers, or general swelling. They are also commonly diagnosed on surveillance Doppler ultrasound where a large perinephric fluid collection is aspirated and found to have a high creatinine content. Nephroscintigraphy or retrograde cystography can confirm the diagnosis. Minor leaks can spontaneously resolve with bladder decompression over several weeks. More significant leaks are approached with immediate exploration and reimplantation of the ureter or with percutaneous maneuvers to maximize drainage for 4 to 8 weeks. Both strategies have their advocates. Proponents of the percutaneous approach report success rates of 90%, avoiding significant morbidity from a reoperation [21].

Ureteral stenosis usually becomes evident months after transplantation when an elevated creatinine leads to a Doppler ultrasound that reveals hydronephrosis. Percutaneous nephrostomy elucidates the location and degree of stenosis as well the opportunity for therapeutic maneuvers including balloon dilatation with a temporary tent tube. If this approach fails, reoperation with operative repair is necessary. Extensive adhesions and lack of graft mobility make this operation quite difficult. On some occasions, reimplanting the distal ureter is possible, but in most cases a ureteroureterostomy (to native ureter) or a ureteropyelostomy (native ureter to the graft’s renal pelvis) is necessary [21].

Perinephric fluid collections after transplantation are common and often innocuous. However, on occasion, they can cause compression of the iliac veins leading to leg edema or compression of the ureter leading to hydronephrosis. In these cases, percutaneous decompression is imperative. Most collections are residual hematomas or seromas and are
self-limited. Lymphoceles, caused from disruption of lymphatic vessels along the external iliac artery, are the exception and can be quite persistent. In these cases, a surgically created peritoneal window must be created to drain the leakage and can often be approached laparoscopically.
NONRENNAL POSTTRANSPLANTATION COMPLICATIONS

Cardiovascular Complications

Cardiac complications are the most common cause of death posttransplantation [22]. For this reason, clinicians are often very particular with the cardiac clearance prior to transplant, but despite careful preoperative evaluation, cardiac complications are not uncommon following transplantation. The immediate function of the transplanted kidney has a very influential effect on the incidence of cardiac complications. Immediate function corrects uremia which in turn improves cardiac index, stroke volume, and ejection fraction. On the other hand, DGF can exacerbate fluid shifts and fluid overload, as well as electrolyte derangements which can tip the patients into congestive heart failure (CHF) [23]. In these cases, expedient HD is essential. Patients who are at high risk for cardiac complications need careful ICU monitoring in the perioperative setting, especially for cases of DGF. This includes patients with long standing diabetes, hypertension, coronary artery disease, and impaired ventricular function. Further monitoring with a pulmonary artery catheter for optimal fluid management may be prudent for the highest-risk patients with diabetes and significant history of cardiac morbidity.

Although somewhat uncommon in the perioperative period, myocardial infarction is one of the major causes of death in the long term. Perioperative myocardial infarctions are more common among patients with diabetes and a history of coronary artery disease. Clinicians should maintain a high index of suspicion with this subgroup, monitoring continuous hemodynamic parameters and serial troponins in an ICU setting. Studies suggest that maintaining the hematocrit above 30% in diabetic patients reduces cardiac morbidity by 24% in the initial 6 months postoperatively [24]. High-risk patients with DGF should have HD initiated expeditiously.

Pericarditis following kidney transplantation occurs in 1% to 3% of patients [25]. The most common culprit is uremia but there are other possible etiologies including: infections (e.g., cytomegalovirus), fluid overload, and medications (minoxidil). Less frequently, bacterial pericarditis develops in recipients with advanced septic complications. In addition to antibiotics, bacterial pericarditis causing cardiac failure, hypotension, or tamponade requires urgent surgical or percutaneous decompression. Any symptoms of pericarditis require ICU monitoring.
Exacerbation of underlying hypertension can be an issue in the postoperative period. Fluid overload and calcineurin (CNI)-induced hypertension can lead to considerable hypertension. Systolic blood pressures above 180 mm Hg or diastolic pressures above 100 mm Hg require intensive monitoring which often includes ICU monitoring with IV antihypertensive infusions (sodium nitroprusside). The patient’s home regimen should be restarted, and abrupt cessation of antihypertensives should be avoided with the exception of angiotensin-converting enzyme inhibitors. Calcium-channel blockers appear to be the best at obviating the renal vasoconstriction induced by CNIs [26]. The mechanism of CNI-induced hypertension is multifactorial, including vascular constriction by reducing prostacyclin and nitric oxide production while increasing serum levels of endothelin-1. Vasoconstriction of the kidney enhances sodium retention and exacerbates hypertension [27].

Hypotension can be catastrophic to the newly transplanted allograft and can lead to graft loss or severe dysfunction. More than just ATN, significant hypotension can perpetuate vascular thrombosis. In the operating room (OR), hypotension can be related to volume depletion or anesthetic agents and should be avoided with appropriate fluid loading using central venous pressure (CVP) monitoring. Induction immunosuppression with thymoglobulin can also lead to hypotension, which should be reversed by slowing the infusion rate. In the postoperative period, brisk diuresis with immediate graft function can lead to inadequate fluid replacement. Cardiac dysfunction and bleeding can also be contributing causes of hypotension.

Uremic patients have a greater incidence of deep venous thrombosis (DVT) compared to the general population, ranging from 1% to 4%. This risk is linked to high-dose corticosteroid therapy in the perioperative period and a hypercoagulable state secondary to decreased fibrinolytic activity and increase in plasminogen activation inhibitors [28]. Other factors for the development of DVT are postoperative immobilization, increased blood viscosity from posttransplant erythrocytosis, cyclosporine, and perinephric fluid collections that can diminish the venous return from the leg. Two-thirds of the time, DVT occurs on the side of the graft. Since the kidney allograft is a high-flow organ, DVT usually terminates at the level of or just distal to the renal vein anastomosis. Elevated hemoglobin levels in conjunction with other risk factors such as old recipient age or diabetes are thought to predispose to DVT and aggressive therapeutic phlebotomy should be used to maintain the hematocrit level at less than 55%.

Once the diagnosis of DVT is established, just as with any other patient, systemic heparin is administered followed by 3 to 6 months of anticoagulation with warfarin. If there is a contraindication to anticoagulation, an inferior vena cava filter can be inserted. In the very
rare instance that phelgmasia cerulea dolens develops, venous thrombectomy and fasciotomy must be performed.

Pulmonary embolism is rare (<1%), but there is an increased risk after kidney transplantation. This is because the coagulation system is activated in the uremic patient after transplantation. After 1 week posttransplantation, the rate of pulmonary embolism is near pretransplant rates. Although rare, if a recipient develops a pulmonary embolism, the mortality rate is about 40%.

Pulmonary Complications

It is not common for kidney transplant recipients to require postoperative ventilator support. Those who do often have pulmonary dysfunction secondary to fluid overload, cardiac dysfunction, or underlying lung disease.

Over-resuscitation in the OR in conjunction with a poorly functioning graft can lead to pulmonary edema. Inadequate pretransplant HD may also contribute. As discussed previously, poor early graft function requires much more precise fluid management to optimize volume status for the graft, without placing the recipient at unacceptable risk for cardiopulmonary complications. Chest radiography in the recovery room to assess pulmonary status should be routine, and may help guide fluid resuscitation. A patient with pulmonary edema and DGF should prompt consideration for HD. Recurrent pulmonary edema may be an atypical manifestation of a kidney graft renal artery stenosis.

*Pulmonary hypertension (PHT)*, although a profound risk factor for death in liver transplant recipients, has not been found to be an independent risk factor for mortality after kidney transplant. Nevertheless, kidney transplant recipients with known PHT may require ICU care postoperatively, guided by PAC monitoring [29].

*Acute respiratory distress syndrome* (ARDS) in kidney transplant recipients is very rare, affecting 0.2% of all patients. A precipitating factor can be induction immunosuppression with antithymocyte globulin. The mortality rate of KTx recipients with ARDS is prohibitive at well over 50% [30].

Metabolic Complications

*Hyperkalemia* is frequently encountered and can be quite dangerous in the perioperative setting making serial serum potassium levels and appropriate treatment indispensable. In the OR, surgical trauma and
transfusion of banked blood can cause hyperkalemia. Postoperatively, hyperkalemia can develop quickly in the setting of DGF. In addition to impaired GFR and decreased plasma aldosterone levels, ATN damage to the distal tubules can contribute to hyperkalemia since the distal tubules are a major site of potassium secretion. Medications are also common culprits. CNIs cause vasoconstriction of the afferent arterioles and damage to the distal tubules leading to hyperkalemia. Other medications that decrease potassium excretion include: trimethoprim-sulfamethoxazole, ACE inhibitors, angiotensin-2 receptor-antagonists, and nonsteroidal anti-inflammatory agents. β-blockers cause hyperkalemia by impeding intracellular potassium entry. The standard therapy is to give IV glucose, insulin, and bicarbonate to rapidly decrease serum potassium, but this does not change the total body potassium content. A potassium-binding resin actually removes potassium from the body but is slow acting. Recipients with hyperkalemia from poor graft function often require HD.

The brisk diuresis from immediate graft function can lead to hypokalemia. Recipients requiring more than 0.3 mEq/kg/h should be placed on a cardiac monitor. Hypomagnesaemia and hypophosphatemia can also result from high-output diuresis. Other causes of hypomagnesaemia include drug-related renal wasting (e.g., cyclosporine, tacrolimus, diuretics, aminoglycosides, and amphotericin B), poor dietary intake, and malabsorption from the gastrointestinal tract. Other causes of hypophosphatemia include secondary hyperparathyroidism, glucocorticoids (inhibit the tubular reabsorption of phosphate), and antacids (which bind phosphate in the gastrointestinal tract).

Infectious Complications

Infectious diseases can be very complex in solid-organ transplant recipients. A comprehensive review is beyond the scope of this chapter, but we will try to cover the germane points for the immediate posttransplantation period. The earliest infections are caused by bacterial infection of breached anatomic sites, including the lungs, blood (indwelling catheters), superficial wounds, and the perinephric space. Viral and fungal infections can occur in the immediate postoperative course but are more common in later periods [31].

The most common infection posttransplant is, not surprisingly, a urinary tract infection, with an incidence of more than 30%. UTIs progress to the more sinister pyelonephritis and bacteremia in about 10% of recipients. Gram-negative bacilli are the cause 70% of the time, but Enterococcus, Staphylococcus, and Candida are other causative pathogens. Risk factors include prolonged bladder catheterization, neurogenic bladder, ureteral stent placement, and ureteral complications.
It is paramount to initiate antibiotic therapy, even in cases of asymptomatic bacteruria. If the infection persists, the ureteral stent should be removed and further diagnostic tests ordered, including voiding cystourethrogram and CT scan [32].

Kidney transplant recipients have a wound infection rate of 1% to 6%. Every effort should be made to prevent wound infections including thorough skin preparation with chlorhexidine, prophylactic antibiotics, and irrigation of the urinary bladder with an antibiotic solution. Wound infections should be treated according to the standard surgical principles of drainage and antimicrobial therapy [33].

Pneumonia is a formidable problem in the posttransplant period, developing in 16% of kidney transplant recipients and carrying a mortality rate of 10% to 13%. In this period, 90% of these infections are bacterial, usually caused by Staphylococcus or nosocomial gram-negative species. Fungal pneumonias are less likely but occur, most commonly in patients with a more intensive immunosuppressive regimen or who had a prolonged prior course of antibiotics [34,35].

The diagnosis of bacterial pneumonia is not always clear-cut. There are many noninfectious causes of fever including atelectasis and medications. If a CXR reveals an infiltrate, a chest CT may delineate the pneumonia. Although there is no consensus on the role of bronchoalveolar lavage (BAL), it may be prudent to obtain a BAL in recipients with pneumonia who do not respond to antibiotic therapy in 48 to 72 hours. If a patient has suspected pneumonia, broad-spectrum antibiotics need to be initiated immediately; antimicrobial therapy cannot wait for culture results in solid-organ transplant recipients. Antifungal therapy should be initiated in appropriate situations. Surveillance cultures should be reviewed to exclude the presence of multidrug-resistant (MDR) bacteria. Antibiotics should later be tailored to culture results [35].

Since kidney transplant recipients have indwelling catheter, arteriovenous fistula, or arteriovenous grafts, they are at risk for bloodstream infections. Catheters should be removed as soon as possible. Staphylococcal species and gram-negative bacilli are the most likely pathogens and should be treated aggressively with IV antibiotics. Persistent bacteremia should prompt suspicions for infective endocarditis. Echocardiogram should reveal cardiac valve vegetation. Treatment is with prolonged antibiotics.

Viral infections can play a sinister role in the later posttransplant period. The predominant offenders are from the herpesvirus genus, including cytomegalovirus (CMV), Epstein–Barr virus, herpes simplex virus (HSV), and varicella-zoster virus (herpes zoster virus, HZV).
Primary infections by HSV are rare but reactivations are common with an incidence as high as 30% for adults and 8% for pediatric recipients. Diagnosis is confirmed by tissue culture or direct immunofluorescent antibody staining using the Tzanck preparation. A PCR test is now available which is thought to be up to two times more sensitive than tissue cultures. Symptomatic HSV infections are common with orofacial and genital lesions. Although much less common, conjunctivitis or corneal ulcerations may develop. Topical 5% acyclovir ointment shortens the duration of viral shedding. Oral acyclovir (200 mg five times per day) is also effective. IV acyclovir (5.0 mg per kg every 8 hours for 7 to 14 days) is used in cases of disseminated disease [36].

CMV infections are rare in the first month posttransplantation but can infect up to as many as 60% of recipients and by some estimates, cause invasive disease in up to 25%. Most infections occur within the first year and are of serious concern. Studies have shown that CMV infections decrease graft and patient survival. We risk-stratify patients based on seropositivity. Donor-seropositive (D+) and recipient-seronegative (R−) is the highest-risk group with an incidence of up to 60%. D+R+ and D−R+ groups have a lower risk profile with an incidence between 20% and 40%. CMV infections are possible in the D−R− group when they occur as primary infections or reactivations [37,38]. Prophylaxis with parental 9-[(1,3-dihydroxy-2-propoxy)methyl] guanine (DHPG) (ganciclovir) or enteral (valganciclovir) forms have successfully reduced rates of infection. Recipients with D+R− (high-risk) group should receive prophylactic oral DHPG for at least 6 months posttransplantation.

In addition to generalized symptoms of fever, malaise, myalgia, and headache, 70% of infected patients have leukopenia. CMV infections can manifest in many different sites, including: neuritis, gastritis, colitis, retinitis, hepatitis, pancreatitis, and nephritis. Most infections occur within the first 6 months. The gold standard for diagnosis is growth in tissue culture; however, PCR quantification techniques are becoming much more common. PCR techniques can detect viremia within 48 hours, allowing for prompt initiation of treatment. The treatment for an established infection is IV DHPG (5 mg per kg every 12 hours if creatinine <1.5 mg per dL with dose adjustment according to graft function). Treatment can be limited by leukopenia (white blood cell count < 3,000 cells per μL) or thrombocytopenia (platelet count < 100,000 per μL), requiring dose reduction or temporary cessation. The treatment course is 14 days of IV DHPG with the addition of CMV hyperimmune globulin for severe cases. Oral DHPG is then continued for 6 months.

EBV infections are often associated with mononucleosis-like symptoms: malaise, fevers, headaches, and sore throat. At its worst manifestation, it can present as widespread posttransplant lymphoproliferative disease (PTLD), a form of B-cell lymphoma. This
usually occurs months to years posttransplantation. Immunosuppression impairs the ability of virus-specific cytotoxic T lymphocytes to control the expression of EBV-infected transformed B cells, leading to polyclonal and monoclonal proliferation of lymphocytes (which constitutes PTLD). Treatment entails cessation of immunosuppression accompanied by anti-CD-20 antibodies (rituximab), and antiviral therapy (e.g., ganciclovir, acyclovir, or anti-CMV immune globulin). Suboptimal responses necessitate conventional lymphoma treatment.

Varicella-zoster virus usually presents as dermalominal skin lesions. Therapy is a 7-day course of acyclovir. Varicella-zoster immune globulin is indicated for seronegative recipients. Recipients are at risk for other viruses as well, including adenoviruses and influenza, papovaviruses, and hepatitis. Human papillomavirus infections are also increased leading to higher incidence of cervical cancer.

Fungal infections are quite frequent and occur in 14% of kidney transplant recipients. Translocation of Candida from the gastrointestinal tract is a common source. *Aspergillus* species infections are common and can be serious. The most common infection is oropharyngeal candidiasis that can be treated with oral nystatin. Systemic fungal infections are usually quite serious and occur in significantly ill patients. Often, recipients are on broad-spectrum antibacterials and have poor graft function. Superinfections have a dismal prognosis. Patients with cerebral, pulmonary, or visceral involvement require significant reduction or cessation of immunosuppression [39].

Azole antifungals (e.g., fluconazole) are the first-line therapy given their safety profile. For life-threatening fungemia, stronger agents such as an echinocandin-like caspofungin, or amphotericin B should be used, especially for non-albicans Candida [40]. Liposomal form of amphotericin B can mitigate some of the agent’s notorious nephrotoxicity. Specific fungal complications include: mycotic pseudoaneurysm from Candida, which often requires graft nephrectomy and IV amphotericin B. *Cryptococcus* and Asperillus can cause severe pulmonary and cerebral infections requiring systemic or intrathecal amphotericin B. *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) can manifest as interstitial pneumonia. Pneumocystic pneumonia (PCP) is rare now that TMP-SMX prophylaxis is the standard of care, but it can be seen with heavily immunosuppressed patients, presenting with fever, dyspnea, and nonproductive cough. Therapy consists of IV TMP-SMX with pentamidine or dapsone serving as alternatives. Reduction of immunosuppression or temporary cessation may also be necessary.

*Mycobacterium tuberculosis* infection is uncommon, infecting about 1% of kidney transplant recipients and is often a result of reactivation of a prior infection. Symptoms include fevers, malaise, night sweats, and weight loss. Sputum and blood samples should be used to identify acid-
fast bacilli. Treatment should be aggressive since mortality rates are high; 6 months of a two- to three-drug regimen or a longer regimen is often required. Treatment agents include isoniazid, rifampin, pyrazinamide, ethambutol, and ciprofloxacin.

**Gastrointestinal and Pancreaticobiliary Complications**

Gastrointestinal tract complications are a major cause of morbidity and mortality for the kidney transplant population.

Peptic ulcer disease (PUD) with its associated complications (perforation, bleeding) is the most common gastrointestinal tract complication. There is some evidence to suggest that the prevalence of PUD is more common among renal failure patients compared to the general population. Historically, it was not uncommon for kidney transplant recipients to have suffered from severe upper GI bleeding; up to 10% of recipients had significant bleeding [41]. These problems declined considerably with the use of H₂ blockers and proton-pump inhibitors. If severe upper gastrointestinal tract bleeding does occur, the standard treatment algorithm should apply. ICU monitoring and resuscitation should be instituted immediately to stabilize the patient followed by conservative treatments with endoscopy with mucosal control measure including submucosal injection of epinephrine when indicated. If the patient is still bleeding, angiographic embolization should be performed which often requires embolization of two arteries. If all of these measures are unsuccessful, as a last resort, emergency gastric surgery should be performed with resection and vagotomy. Immunosuppression should be minimized during the perioperative period. A high incidence of CMV infection has been observed in peptic ulcers from kidney transplant recipients. Tissue samples should be tested for CMV and if positive, IV DHPG and anti-CMV immune globulin treatments initiated.

Small-bowel obstruction can occur following intra-abdominal placement of organs as is done with pediatric kidney transplantation or simultaneous pancreas–kidney transplantation in adults. The vast majority of adult kidney transplantations are placed in the retroperitoneum so small-bowel obstructions are usually not related to the operation; however, small bowel can incarcerate through an inadvertent tear in the peritoneum made during the dissection. More likely, obstruction is related to previous intra-abdominal procedures, infections, or PTLD in the small bowel or mesentery.
Colonic perforation and lower gastrointestinal tract hemorrhage are the most common lower gastrointestinal tract complications encountered, but have a very low incidence overall. Colonic perforation occurs in 1% to 2% of KTx recipients and is most commonly owing to diverticulitis, ischemic colitis, CMV colitis, and occasionally, stercoral ulceration. Colonic perforation in KTx recipients carries a very high mortality rate—20% to 38%. Immunosuppression complicates the diagnostic picture and is associated with high mortality rates. Peritoneal signs are usually absent in immunosuppressed kidney transplant recipients. The progression to septic shock can be very rapid. A successful outcome depends on maintaining a high index of suspicion, liberal use of imaging studies, and a low threshold for exploration. Diverting colostomies have been associated with better outcomes than other approaches [42–45].

Kidney transplant recipients, especially patients with polycystic kidney disease, have a greater incidence of colonic diverticulitis with higher rates of perforation. Steroids are thought to be responsible for this difference since they not only mask the symptoms but impair the patient’s ability to localize and contain the infection. Historically, diverticular perforations had a disastrous prognosis, but recent experience suggests decreasing mortality rates. This is likely owing to the widespread acceptance of the principle that immunosuppressed patients need prompt surgical intervention. It may be prudent to perform sigmoid resections with a Hartmann pouch and diverting colostomy compared to the general population where primary anastomosis is often advocated. Given the significant morbidity from diverticulitis in this population, some surgeons advocate sigmoidectomy prior to transplantation for candidates with a single episode of diverticulitis [46,47].

Ischemic colitis is associated with significant arterial disease, immunosuppression, antibiotic therapy, and hypotension—so it is no surprise that there is a higher incidence in the kidney transplant population. On rare occasions, even young transplant recipients without significant risk factors can have ischemic colitis, with no apparent explanation. Ischemic colitis may be segmental or pancolic [48,49].

Pseudomembranous colitis caused by Clostridium difficile is being increasingly recognized. Due to immunosuppression, it can rapidly progress to toxic megacolon and perforation with a grim prognosis. Stool assays in conjunction with the clinical picture confirm the diagnosis. On occasion, visualization of the pseudomembranes on colonoscopy is necessary. Patients can be treated conservatively with metronidazole (250 mg four times daily for 10 days) or oral vancomycin (125 mg every 6 hours for 10 days), but there should be a low threshold for colonic resection when a patient’s clinical condition deteriorates.

Neutropenic enterocolitis is associated with profound neutropenia and
invasion by clostridial organisms; most commonly, *Clostridium septicum*. Treatment is with metronidazole and again, low threshold for surgical intervention. Infectious colitis is frequently owing to CMV infections but can also be due to bacterial, viral (e.g., herpes), or fungal pathogens. Diagnosis is confirmed by stool cultures, and if necessary, endoscopic biopsies. Empiric antibiotics should be started quickly with later tailoring of the regimen based on culture results. In most cases of infectious colitis, surgical intervention should be avoided [50].

Ogilvie syndrome or acute colonic pseudo-obstruction has an incidence of 1.5% among kidney transplant recipients. It is a paralytic colonic ileus that can cause pronounced cecal dilation and eventual rupture. The first line of therapy is conservative with nasogastric decompression, and neostigmine. If this fails, endoscopic colonic decompression can be tried. The last line of therapy is surgical resection. Again, the principle of prompt surgical intervention holds. Immunosuppression should be reduced. Rejection is very uncommon in patients with severe infections or extremis [51].

In addition to the common causes of lower gastrointestinal tract bleeding, transplant-specific pathologies are common in this population, including CMV colitis and fungal ulcerations. H$_2$ blockers and antacids that promote fungal overgrowth owing to achlorhydria can promote fungal ulceration. Steroids can also promote ulcers and impair the reparative mechanisms of the bowel wall. Additionally, uremia and diabetes result in colonic distention and impaction promoting colonic ulcers. Prompt diagnostic colonoscopy and treatment is essential [52].

Pancreatitis is also more common in the kidney transplant population compared to the general population. One to six percent suffer from an episode of pancreatitis. There are numerous transplant-specific risk factors, including: (1) immunosuppressants (e.g., corticosteroids, azathioprine, cyclosporine) and diuretics (e.g., furosemide, thiazide diuretics); (2) hypercalcemia with or without hyperparathyroidism [53]; (3) infections (e.g., CMV, HSV) [54]; (4) previous episodes of pancreatitis (uremia); and (5) cholelithiasis (i.e., related to cyclosporine). There is also speculation of a phenomenon called rejection pancreatitis where host antibodies react not only to the graft (vascular rejection) but also with antigens on the surface of the pancreas cells (vascular pancreatitis). The most frequent causes of pancreatitis in the general population, biliary tract disease and alcoholism, are not as common in the kidney transplant population [55,56].

Since hyperamylasemia is not uncommon in uremic patients, owing to reduced amylase clearance from the kidneys, the amylase/creatinine clearance ratio is a more sensitive index of pancreatitis. The degree of hyperamylasemia in not thought to be a prognostic factor. A contrast-enhanced CT scan is important for staging. Conservative therapy should
be initiated. Any evidence of hemorrhagic or necrotizing pancreatitis requires ICU monitoring and careful fluid resuscitation with cardiac monitoring. Additionally, immunosuppression should be reduced and broad-spectrum antibiotics initiated when infection is suggested by imaging studies. Percutaneous drainage or aggressive surgical therapy should be pursued if there is any evidence of infected necrosis, including removal of all necrotic material in multiple trips to the OR that is sometimes necessary to achieve sufficient drainage by irrigation of the abdominal cavity. Overwhelming sepsis is the common cause of death. Furthermore, the mortality rate for posttransplant pancreatitis is higher than for other forms of pancreatitis. It is therefore essential to promptly initiate broad-spectrum antibiotics and reduce immunosuppression.

There is no clear evidence for prophylactic cholecystectomy for asymptomatic cholelithiasis in the pretransplant screening. In the posttransplant period, acute choleylitis should always be considered in patients with abdominal pain and sepsis. Acalculous cholecystitis should be considered with complicated posttransplant courses and prolonged hospital stays. Biliary scintigraphy is often necessary to establish the diagnosis. If a patient is not clinically stable enough for a formal operation, image-guided cholecystectomy drainage should be pursued.

**Neurologic Complications**

The incidence of life-threatening central nervous system (CNS)–related complications in the immediate posttransplant period is 1% to 5% [57–59]. The patient population is prone to comorbidities that are a setup for cerebrovascular events, including: diabetes, hypertension, hyperlipidemia, hypercoagulability, uremia, and advanced age. The most common cerebrovascular events, infarct, TIA, and hemorrhage, peak during the first few months postoperatively. The prognosis of hemorrhage is grim. Patients with strokes and TIAs should be treated immediately with heparin and aspirin. If there is an ulcerated carotid lesion or a stenosis that is severe but accessible, a carotid endarterectomy should be pursued.

CNS infections have a wide spectrum of severity, but all are considered serious. Infections are caused by bacteria (e.g., *Listeria monocytogenes*, *Pseudomonas* species), viruses (e.g., CMV, HSV), fungi (e.g., *Cryptococcus, Aspergillus, Mucor*), and parasites (*Toxoplasma*). *L. monocytogenes* is the most common infectious organism and usually causes meningitis. *Aspergillus* species can cause brain abscesses.
Rhinocerebral mucormycosis infection can cause cavernous sinus thrombosis and rapid death. Dissemination of CMV may include the CNS, although the overall incidence is low [60]. Acute polyradiculoneuritis has also been associated with CMV infections. Similarly, dissemination of the VZV can involve the CNS or facial nerve (Ramsay–Hunt syndrome). It is crucial to diagnose and treat these infections early and aggressively. Intrathecal administration of antimicrobial drugs or drainage for recipients with brain abscesses may be necessary.

Seizures are most commonly associated with excessively high CNI serum levels. Hypertension and hypomagnesaemia may predispose recipients to seizure activity. Diagnosis can be confirmed with a brain MRI showing PRES (posterior reversible encephalopathy syndrome). PRES occurs in about 0.35% of kidney transplant recipients [61]. Treatment includes a reduction in CNI dosing or switching to a non-CNI immunosuppressant, in addition to anticonvulsants. ICU monitoring is mandatory. Tacrolimus more frequently causes neurologic problems than cyclosporine. Other forms of CNI neurotoxicity include tremor, headaches, paralysis, quadriplegia, and coma.
CURRENT CHALLENGES IN KIDNEY TRANSPLANTATION

Despite the many advances in kidney transplantation, several challenges remain (Table 57.1). During the past decade, the proportion of candidates on the active kidney transplantation waiting list >50 years of age has increased from 44% to 58% and those with diabetes and hypertension have increased from 24% to 28% and 17% to 22%, respectively. To maintain excellent short-term outcomes, an exhaustive pretransplantation cardiovascular evaluation followed by intense posttransplantation critical care has become mandatory for this high-acuity cohort of patients [8,9].

KTx, kidney transplantation.
Mortality on the waiting list continues to stimulate the adoption of innovative desensitization protocols to allow high-risk recipients a transplantation opportunity. This, in turn, must be met with equally innovative therapies when antibody-mediated rejection occurs in the early postoperative period. Attempts at modulating the complement system are underway to mitigate early posttransplant injury in the allograft [62].

1985.

INTRODUCTION

From early experimental animal model implantations conducted in the 1950s, to the first successful liver transplant performed by Dr. Starzl in 1963, liver transplantation has evolved to become a safe and widely accepted treatment for patients with end-stage liver disease (ESLD) [1]. The current 1-year survival rate in recipients of deceased donor organs is approximately 91%, owing in part to improvements in surgical procurement and transplantation techniques, more effective immunosuppressive regimens, individualized approaches to immunosuppression, improved perioperative and postoperative critical care, and improvements in the management of rejection and infection (Source: OPTN data as of November 27, 2015. [http://optn.transplant.hrsa.gov](http://optn.transplant.hrsa.gov). Accessed December 1, 2015).

Despite these substantial improvements, liver transplantation is a major abdominal surgical procedure that confers significant risk for a variety of postsurgical and medical complications. The content of this chapter addresses the critical care of these complex, often critically ill patients, from the intraoperative through the immediate postoperative period, reviewing the management of selected posttransplant complications. Care of the live donor is also described. Detailed
discussions regarding care of the patient with ESLD, approaches to immunosuppression management, and the diagnosis and management of rejection, infection, and malignancy for transplant recipients are found in other sections of this textbook.
ORGAN ALLOCATION AND DISPARITY

Expanding the Donor Pool

As liver transplant outcomes have improved, the indications for liver transplantation have expanded, and the number of individuals waitlisted for liver transplant has increased dramatically. According to Organ Procurement and Transplantation Network (OPTN) data, 15,064 patients were listed for liver transplant as of November 27, 2015. In the United States, 6,729 liver transplants were performed in 2014. Approximately 4% of liver transplants performed each year are from live donors (Source: OPTN data as of November 27, 2015; http://optn.transplant.hrsa.gov. Accessed December 1, 2015).

Given the growing problem of disparity between the number of liver transplant candidates and available donor organs, expansion of the donor pool has attracted increased interest. Donors with livers that are considered marginal are now allocated to carefully selected recipients, whereas they may not have been deemed acceptable for transplantation in the past. Although these so-called extended criteria donors have created opportunities for candidates who may not otherwise have received an organ, they are associated with an increased rate of primary nonfunction (PNF). In 2006, a retrospective study of more than 20,000 donors identified a number of factors associated with an increased risk of graft loss. This work contributed to the development of a “donor risk index,” which is used to predict the rate of graft survival. Characteristics associated with a relative risk of at least 1.5 for liver graft loss include donor age over 60 years, donation after cardiac death, and use of partial/split grafts. Other donor factors, such as age between 40 and 60 years, African American race, and cerebrovascular accident, are also associated with an increased risk for graft loss, though to a lesser extent. Use of the donor risk index may help to optimize donor–recipient matching. Innovative surgical procedures have also been used to increase the donor pool, including living donor liver transplantation and split-liver transplantation. These procedures are each associated with unique problems, as will be discussed below.

DCD Organs

In recent years, the use of organs from donors after cardiac death (DCD)
has emerged as an important source of grafts [2]. DCD donors have severe neurologic injury without meeting criteria for brain death [3–5]. In the United States in 2009, 4.6% of liver transplants performed were from DCD donors, up from 3% in 2004 [2–5]. Kidneys from DCD donors, despite their higher rate of delayed graft function, provide similar graft survival as do kidneys from brain death donors [6]. Results for liver transplantation with grafts from DCD donors have been mixed, and individual centers have reported outcomes ranging from excellent to very poor. An SRTR review of over 1500 DCD liver transplants between 2001 and 2009 revealed a 3-year patient survival of 64.9%. Furthermore, 13.6% required retransplantation [7]. The principal problem with the use of DCD livers is the risk of biliary complications and the development of ischemic cholangiopathy, which has been reported to occur in 16% to 29% of cases, often requiring retransplantation [8].

### Reduced-Size and Split-Liver Transplantation

In reduced-size liver transplantation (RSLT), a whole deceased donor graft is tailored to fit the recipient. A portion of the liver, such as the right lobe, is resected and discarded, and the remaining left lateral segment is used for the transplantation. In split-liver transplantation (SLT), an adult deceased donor liver is divided into two grafts: the left lateral segment and the remaining right trisegment (right lobe plus segment 4). Both segments can then be utilized for transplantation. For most adult recipients with ESLD, the small graft size with this approach would not be sufficient. Thus, while this approach may be beneficial for pediatric transplantation, it does not serve to significantly increase the adult donor pool [9]. With appropriate donor and recipient selection criteria, however, SLT may be considered for two adult recipients.

### Living Donor Liver Transplantation

Living donor liver transplant (LDLT) involves removing a segment of the liver from an adult donor and transplanting the segment into a carefully selected recipient. This approach typically provides sufficient liver tissue for a recipient. With LDLT, the transplant is optimally performed before the recipient’s health deteriorates significantly, thereby shortening the wait time. In LDLTs for pediatric recipients, the left lateral segment is used; for adult recipients, however, depending on the donor and recipient size and the liver volume, either right or left lobe could be considered. In 2001, 524 LDLTs were performed in the United States, of the 5,195 liver transplants performed that year (10.1%) (OPTN data as of November 27, 2015, source [http://optn.transplant.hrsa.gov](http://optn.transplant.hrsa.gov)). Since that all-time high, approximately 250 liver transplants each year have been LDLTs; in 2014, 280 of the 6,729 (4.2%) liver transplants performed were from live

The main disadvantage of LDLT is the peri- and postoperative risk to an otherwise healthy donor. All potential live liver donors are carefully evaluated through a detailed screening process, including assessment by a hepatologist, donor surgeon, independent donor advocate, social worker, psychiatrist, and other providers as indicated during the evaluation. Standardized radiologic and laboratory evaluation is performed in order to detect the presence of any underlying medical issues. This detailed screening process is conducted in order to ensure that the donor is medically healthy and able from both a physical and a psychosocial perspective to undergo liver donation. The decision to proceed with live liver donation occurs following this extensive evaluation, after careful consideration and discussion of the risks and potential complications of liver donation.

**Hepatitis B–Positive Donors**

Careful allocation of organs from donors with hepatitis B virus (HBV) infection may safely expand the donor pool. The risk of transmission of HBV varies depending on the serologic status of both donor and recipient, with the highest risk observed in transplantation of grafts from donors with active HBV (HBsAg+ or HBV DNA+ donors) to naïve recipients. Liver graft recipients are at highest risk for acquisition of de novo HBV, as compared with recipients of other grafts. Prevention of transmission includes use of universal prophylaxis with newer generation antivirals such as entecavir, and occasionally the targeted use of hepatitis B immune globulin (HBIg) intra- and postoperatively, for a specified duration. These strategies significantly lower the risk of transmission of HBV, and make this a reasonable approach, particularly for patients who may not otherwise receive a standard graft in a timely manner. With the use of antiviral prophylaxis, with or without HBIg, excellent outcomes have been demonstrated with transplantation of HBV core antibody-positive donor grafts to immune (vaccinated or natural immunity) recipients. The risks of transmission of HBV must be discussed with the transplant candidate in advance of transplantation, and the candidate must provide informed consent for the transplantation of organs from donors with past or active HBV infection. A comprehensive consensus guideline was recently published that provides guidance with regard to the management of recipients of grafts from donors with active or prior HBV infection [10].

**Hepatitis C–Positive Donors**

Historically, transplantation of grafts from donors with a past history of
hepatitis C virus (HCV) infection was reserved for recipients with active genotype 1 HCV infection. Outcomes in this setting were demonstrated to be equivalent to those in HCV-positive recipients of HCV-negative grafts [11]. For optimal outcomes, grafts from HCV-positive donors should be from younger donors with no significant liver fibrosis or inflammation. Grafts from older donors may be associated with more rapidly progressive fibrosis related to HCV posttransplant. In the new era of effective treatment of HCV-infected recipients with direct acting antivirals, the approach to the use of HCV-positive grafts for HCV-positive recipients will likely change. Data and guidelines in this area are rapidly evolving.

**PHS Increased Risk Donors**

Some donors engage in behaviors that may put them at increased risk for infections that can be transmitted by blood or body fluids. These infections include human immunodeficiency virus (HIV), HBV, and HCV. Donors with these risk behaviors are referred to as Public Health Service (PHS) Increased Risk Donors (Table 58.1). Revised guidelines for the assessment of PHS Increased Risk Donors, and for the monitoring of recipients of grafts from these donors, were published in 2013 [12]. Prior to organ procurement, potential donors are tested for all of these viruses using both serologic tests and nucleic acid tests (NAT). Even in the setting of negative serologic and NAT testing, PHS Increased Risk Donors, who constitute up to 9% of the donor pool, may harbor low levels of these viruses, and may pose a risk for transmission of viral infection from donor to recipient. This typically occurs during a “window period” of infection, when a donor has recently been exposed to one or more of these viruses and has not yet developed a measurable antibody response to the virus(es). The advent of NAT testing has decreased this window period dramatically, but a small risk of transmission still exists. With the active antiviral treatments that are now available for HIV, HBV, and HCV, utilization of organs from PHS Increased Risk Donors is a very reasonable option for carefully selected recipients who may not otherwise receive an organ in a reasonable time frame, and for whom the risk of death from end-stage organ disease is more significant than the risk of transmission of infection from a PHS Increased Risk Donor. The risks of transmission must be discussed with the transplant candidate in advance of transplantation, and the candidate must provide informed consent for the transplantation of PHS Increased Risk organs.

CAUSES OF LIVER FAILURE AND LIVER TRANSPLANT CANDIDATE SELECTION

Indications for Liver Transplant

Within the array of available options for the management of patients with chronic liver disease, liver transplantation is the most definitive one. However, not every patient may benefit from a transplant, and risks and benefits of either option should be carefully evaluated for each individual patient. Typically, well-compensated cirrhotics have a low mortality risk secondary to their underlying liver diseases and may be managed medically. However, patients with signs of hepatic decompensation have a poor prognosis without a transplant and should be considered for transplantation. Furthermore, well-selected patients with certain malignancies confined to the liver may benefit from liver transplantation. In particular, patients with hepatocellular carcinoma may have excellent long-term disease-free outcome after liver transplantation.

As hepatic fibrosis progresses and liver function deteriorates, signs and symptoms of decompensated liver disease appear. Decompensated cirrhosis is defined as the presence of any one of the following, which leads to an acute care hospitalization: (1) portosystemic encephalopathy, (2) variceal hemorrhage, (3) spontaneous bacterial peritonitis, (4) hepatorenal syndrome or acute kidney injury in the setting of cirrhosis, or (5) hepatic hydrothorax. Critical care of patients with decompensated cirrhosis and fulminant hepatic failure is addressed in Chapters 206 and 207. Portal hypertension can lead to the development of esophageal varices and portal hypertensive gastropathy and eventually hemorrhage. Ascites may require large volume paracentesis and can be further complicated by spontaneous bacterial peritonitis (SBP) [13]. As portal blood is shunted away from the liver and ammonia is insufficiently cleared from the circulation, hepatic encephalopathy develops. Other complications of ESLD include hepatorenal syndrome (HRS), hepatopulmonary syndrome, portopulmonary syndrome, protein malnutrition and muscle wasting, and severe weakness and fatigue. Identifying and managing patients with decompensated cirrhosis or fulminant hepatic failure who may be candidates for orthotopic liver transplant (OLT) is a complex process, with interprofessional collaboration between medical and surgical services. For patients who are hospitalized with decompensated cirrhosis and who undergo a transplantation evaluation while in the hospital, coordinated care involving the transplant and critical care teams is crucial to facilitate
Causes of Chronic Liver Disease

A variety of chronic liver diseases account for the majority of indications for liver transplantation, as compared with transplants for acute liver disease. The most common causes of chronic liver disease in North America include alcohol use, hepatitis C virus (HCV) infection, and nonalcoholic steatohepatitis (NASH). Autoimmune hepatitis may also lead to cirrhosis, primarily in women, and may develop either acutely or over a period of years [14]. Cholestatic disorders are also an important cause of chronic liver disease. In adults, the most common cholestatic causes of chronic liver disease are primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). In children, biliary atresia is the most common cause of cholestatic liver disease. Metabolic diseases that can cause chronic liver injury and cirrhosis include hereditary hemochromatosis, \( \alpha_1 \)-antitrypsin deficiency, and Wilson disease [15].

Hepatocellular carcinoma (HCC) may develop as a complication of cirrhosis from any cause, but is most commonly seen in patients with hepatitis B virus (HBV) infection, HCV infection, hemochromatosis, and tyrosinemia. The best transplantation candidates are those with a single lesion less than 5 cm in size or with no more than three lesions, the largest no greater than 3 cm in size (known as the Milan criteria). Transplantation of patients with HCC lesions outside of these criteria is usually associated with higher recurrence rates, although some centers have shown acceptable 5-year survival in patients that have tumors that slightly exceed the Milan criteria [16,17]. Other diseases that may lead to chronic liver failure that are potentially amenable to treatment with a transplant include Budd–Chiari and polycystic liver disease.

In order to determine the cause of ESLD, if not already known, and to begin the liver transplant evaluation process, a comprehensive laboratory evaluation is performed, to identify the etiology of cirrhosis, to determine the presence of comorbid conditions, to rule out active infectious processes requiring treatment before transplantation, and to guide vaccination strategies.

Causes of Fulminant Hepatic Failure

Fulminant hepatic failure (FHF) is defined as the development of hepatic encephalopathy and profound coagulopathy rapidly after the onset of
initial symptoms, such as jaundice, in patients without preexisting liver disease. UNOS criteria for FHF (OPTN Policy 9.1.A) include all of the following:

1. age at least 18 years old at the time of registration for transplant, and
2. life expectancy without a liver transplant of less than 7 days and at least one of the following conditions:
   a. acute decompensated Wilson Disease or
   b. fulminant liver failure, without preexisting liver disease and currently in the ICU, defined as the onset of hepatic encephalopathy within 8 weeks of the first symptoms of liver disease, and has at least one of the following criteria:
      i. ventilator dependency
      ii. requiring dialysis, continuous venovenous hemofiltration (CVVH), or continuous venovenous hemodialysis (CVVHD)
      iii. has an international normalized ratio (INR) greater than 2.0

Alternative criteria for FHF include the King’s College Criteria, which are listed in Table 58.2.

- Unfavorable etiology (Wilson Disease, idiosyncratic drug reaction, seronegative hepatitis)

ALF, acute liver failure; OLT, orthotopic liver transplant; INR, international normalized ratio.

The most common causes of FHF in the Western world include acetaminophen overdose, acute viral hepatitis, various drugs and hepatotoxins, and Wilson disease; often, however, no cause is identified [18]. Treatment consists of appropriate critical care support and providing patients with time for spontaneous recovery. The prognosis for spontaneous recovery depends on the patients’ age (those younger than 10 and older than 40 years have a poor prognosis), the underlying cause, and the severity of liver injury (as indicated by degree of hepatic encephalopathy, coagulopathy, and kidney dysfunction) [19,20]. A subset of patients may have delayed onset of hepatic decompensation that occurs 8 weeks to 6 months after the onset of symptoms. This condition is often referred to as subacute hepatic failure; these patients rarely recover without a transplant.

MELD and PELD

The severity of illness and prognosis of patients with chronic liver disease can be estimated by a variety of scoring models, including the Childs–Pugh–Turcotte score and the MELD score. The latter is now widely used in the United States for the allocation of organs. It is based on a predicted 3-month mortality for patients awaiting a liver transplant and uses three laboratory values to generate a score that determines priority for liver transplantation. The three laboratory values used are serum bilirubin, serum creatinine, and INR.

For pediatric patients, the scoring system is somewhat different. The PELD (pediatric ESLD) score is calculated on the basis of the following factors: serum bilirubin, albumin, and INR, the age of the patient (additional points if the patient is <1 year old), and growth trajectory (additional points if the patient has growth failure) [21]. MELD and PELD calculators can be readily found online, including on the OPTN website (http://optn.transplant.hrsa.gov/converge/resources/MeldPeldCalculator.asp?index=98).

Contraindications for Transplant
Absolute contraindications to liver transplantation are few and have decreased with time. There are no specific age or weight limits for recipients. Contraindications include irreversible cardiac or pulmonary disease, uncontrolled active systemic infection and active extra-hepatic malignancy. HCC patients with metastatic disease, obvious vascular invasion, or significant tumor burden are not good transplant candidates. Patients with other types of extra-hepatic malignancy should be deferred for at least 5 years after completing curative therapy before a transplant is attempted.

Currently in the United States, the most common contraindication to a liver transplant is ongoing, active substance abuse. Before considering patients for a transplant, most centers require a documented period of abstinence, demonstration of compliant behavior, and willingness to pursue a chemical dependency program.

Unique to patients with chronic liver disease, a transplant may be contraindicated in the presence of severe treatment-resistant porto-pulmonary syndrome or pulmonary hypertension. Hepatopulmonary syndrome is characterized by impaired gas exchange, resulting from intrapulmonary arteriovenous shunts. These shunts may lead to severe hypoxemia, especially when patients are in the upright position (orthodeoxia). A transplant may be contraindicated if intrapulmonary shunting is severe, as manifested by hypoxemia that is only partially improved with high inspired oxygen concentrations. Pulmonary hypertension (mean pulmonary artery pressure >25 mm Hg in the setting of portal hypertension) is seen in a small proportion of patients with established cirrhosis. Its exact cause is unknown [22]. Diagnosing pulmonary hypertension pretransplant is critical, because major surgical procedures in the presence of irreversible pulmonary hypertension are associated with a very high risk of mortality. The initial screening is usually performed with transthoracic Doppler echocardiography (TTE), which can estimate pulmonary arterial systolic pressure when tricuspid regurgitation is present. TTE presents a sensitivity of 97% and a specificity of 77% in diagnosing pulmonary hypertension in the setting of liver failure. In patients with elevated pulmonary arterial systolic pressure (>50 mm Hg), a more invasive assessment (right heart catheterization) is recommended. It has been shown that perioperative mortality is directly proportional to the mean pulmonary artery pressure (mPAP) and pulmonary vascular resistance. For these reasons, most transplant centers consider a mPAP greater than 35 mm Hg to be an absolute contraindication for transplant. If the mPAP can be lowered
below that value using medications (epoprostanol, sildenafil), the patient can still be considered for transplant [22].

Another absolute contraindication for liver transplantation, in case of acute liver failure, is the presence of unresponsive cerebral edema with sustained elevation of intracranial pressure (>50 mm Hg) and a persistent decrease in cerebral perfusion pressure (<40 mm Hg).
INTRAOPERATIVE MANAGEMENT

The liver transplant operation itself may be divided into three phases: recipient hepatectomy, anhepatic phase, and reperfusion. The recipient hepatectomy phase involves mobilizing of the recipient’s diseased liver in preparation for its removal. Adequate exposure is crucial for the safety of the procedure. The most commonly used incision is a bi-subcostal incision with upper midline extension. This allows for sufficient exposure of the liver hilum, inferior vena cava (IVC), and most of the abdominal aorta, in case access is needed during the procedure. The initial step in hepatectomy includes dissection of the hepatoduodenal ligament. Branches of hepatic artery and the common bile duct are ligated and transected close to the liver. The portal vein is then isolated. There are two major approaches to recipient hepatectomy; the conventional technique entails removal of the hepatic portion of the native IVC and replacing it with the donor IVC. This requires temporary interruption of portal and inferior caval flow, causing decreased venous return to the heart. Many centers routinely employ a venovenous bypass (VVB) system during this time: blood is drawn from the lower body and bowels via a cannula in the common femoral vein and portal vein, and returned through a central venous cannula in the upper body. Potential advantages of bypass include improved hemodynamic stability, reduction of bleeding and bowel edema from an engorged portal system, and avoidance of elevated venous pressures in the renal veins. However, many centers selectively use VVB for patients without portal hypertension or for those patients who demonstrate hemodynamic instability with a trial of caval clamping. The added complexity of VVB combined with its potential complications, which include air embolism, thromboembolism, hypothermia, hemodilution, cannula and incision-related morbidity, trauma to vessels, and incremental costs, has led to the development of the cava preserving technique. Here, the liver is dissected off the IVC, and all the short hepatic veins entering the IVC are individually ligated and transected. The main hepatic veins (right, middle, and left) are then isolated and transected after placement of a vascular clamp. Although use of either technique is mainly dictated by the preference of individual surgeon, a recent randomized study did demonstrate increased risk of posttransplant renal dysfunction using the conventional technique [23].

Given the presence of existing coagulopathy and portal hypertension associated intra- and retroperitoneal varices within the recipient, the hepatectomy may be very challenging and provoke excessive blood loss. Rapid infusion devices and use of intraoperative cell salvage machines are therefore extremely helpful. Liver transplantation is, by necessity, a
team effort. Good communication between the surgeons and the anesthesia team is imperative throughout the case.

Once the in- and outflow of the liver are obstructed, the recipient liver is removed and the patient is considered anhepatic. At this time, the majority of the bleeding has subsided and the induction immunosuppression is administered. Next, the donor liver is anastomosed to the appropriate structures, to place the new liver in an orthotopic position. The suprahepatic caval anastomosis is performed first, followed by the infrahepatic cava. In the case of the piggyback technique, the donor’s suprahepatic cava is anastomosed to the recipient’s confluence of the hepatic veins. Once the portal vein anastomosis is performed, the caval and portal clamps are removed, allowing reperfusion of the new liver. The hepatic artery is then anastomosed.

The reperfusion phase may be associated with dramatic changes in the patient’s hemodynamics, with hypotension and the potential for serious cardiac arrhythmia. Many centers routinely rinse the graft through the portal vein prior to reperfusion to remove excessive potassium and accumulated metabolites from the graft, in order to reduce the risk of postreperfusion syndrome. Although there are no standard rinsing protocols [24], we routinely use cold lactated Ringer solution. Furthermore, severe coagulopathy may also develop because of the release of natural anticoagulants from the ischemic liver or active fibrinolysis. Clot firmness, measured by thromboelastometry, is an excellent tool in the assessment of intraoperative coagulopathy and helps to guide treatment. Fresh frozen plasma, platelet concentrate, and fibrinogen are often needed to correct the postreperfusion coagulopathy [25].

For pediatric patients (particularly infants and small children), the chance of finding a size-matched cadaver graft may be very small; the vast majority of cadaver donors are adults. Reduced-size liver transplants, living related liver transplants, and split-liver transplants are used to size-adjust the donor liver to the recipient body.

For living donor (LD) liver transplantation, the recipient operation is not greatly different from whole-organ deceased donor liver transplants. The recipient hepatectomy is performed in cava preserving fashion. The LD graft typically has a single hepatic vein that is anastomosed to the recipient’s right hepatic vein orifice or directly anastomosed to the IVC. Furthermore, the graft often has segmental veins (segments 5 and 8 in case of right lobe graft) that may require reconstruction to ensure adequate outflow and avoid venous congestion. Many centers perform porto-systemic shunts in all or selected patients, in order to protect the partial graft against high portal flow and pressure, which can increase the risk of hepatic artery thrombosis. Inflow to the graft can be reestablished
by anastomosing the donor’s portal vein and hepatic artery branch to the corresponding structures in the recipient. Bile duct anastomosis is performed between the graft’s hepatic duct(s) and the patient’s common bile duct or hepatic duct branches. Alternatively, a Roux-en-Y hepaticojejunostomy can be used for biliary drainage.
POSTOPERATIVE MANAGEMENT

The postoperative course after liver transplant can range from very straightforward to extremely challenging. Several factors influence the pace and progression of recovery; among the most important ones are the preoperative status of the patient (MELD score, presence of hepatorenal syndrome, hepatopulmonary syndrome, and malnutrition), graft quality (graft size, degree of steatosis, ischemic insult and ischemia–reperfusion injury), and development of postoperative complications. Early postoperative care for all liver recipients includes: (1) initial resuscitation and supportive care for the recovery of major organ systems; (2) assessment of the graft function and institution of immunosuppression; and (3) monitoring and treatment of postoperative complications.

Initial Resuscitation and Recovery of Major Organ Systems

Transplant surgery typically provokes a major physiologic stress to otherwise very sick patients. Patients with ESLD often have portal hypertension, coagulopathy, thrombocytopenia, and dysfunction involving organ systems other than the liver. The surgery itself causes rapid hemodynamic changes, massive fluid shifts, and alterations in electrolyte and acid–base balances. Hence, patients are usually kept under sedation, mechanically ventilated, and closely monitored in an intensive care setting for several hours following transplantation. This delay in extubation is intended to achieve and maintain adequate equilibrium in all organ systems in a highly controlled setting, while the newly grafted liver supersedes the previously dysfunctional cirrhotic liver.

When the patient is hemodynamically stable and sufficient liver function has been established, sedation is discontinued and the patient is allowed to regain consciousness. Once the patient demonstrates ability to protect his/her airway and maintain sufficient ventilation and oxygenation, the endotracheal tube is removed. Adequate fluid management, respiratory physiotherapy, incentive spirometry, and early ambulation will help to reduce the risk of respiratory complications.

The functions of the heart and liver are closely related. Chronic heart failure can cause liver dysfunction owing to congestion; similarly, certain conditions that lead to cirrhosis, such as chronic alcohol abuse and hemochromatosis, can also affect the heart. The state of cirrhosis itself impacts the heart as well [26]. A study of a cohort of 403 liver transplant recipients revealed 7% risk of myocardial infarction within the first 30
days posttransplant [27]. To minimize this risk, continuous hemodynamic surveillance is recommended; ECG and blood pressure monitoring through an arterial line, volume monitoring by use of a pulmonary artery catheter, transesophageal echocardiography or pulse dye densitometry should be considered. Information obtained should be used to ensure adequate perfusion of the graft and other vital organs. The preoperative hyperdynamic circulatory state will often persist into the postoperative period. Later, as hepatic function improves, the cardiac index progressively declines, and the SVR increases toward normal values. However, the myocardial dysfunction that is often seen early in the reperfusion phase may persist, with decreased compliance and contractility of the ventricles. The cause of this myocardial depression is unclear, but may be related to the release of vasoactive substances after reperfusion of the ischemic liver and decompression of the portal circulation. The usual treatment is to optimize preload and afterload, and use inotropic agents such as dopamine or dobutamine, as indicated.

To assess for possible bleeding, serial hematocrit measurements should be taken, initially every 4 to 6 hours. Coagulation parameters (prothrombin time, partial thromboplastin time, thrombin time) need to be carefully monitored because of frequent coagulopathy, most likely related to intraoperative blood loss and temporary ischemic damage of the revascularized new liver. Other laboratory values that must be monitored include serum transaminases and serum bilirubin. Normalization of these values, along with improvement in mental status and renal function, are valuable indicators of good graft function.

Fluid management, electrolyte status, and renal function require frequent evaluation after surgery. Most liver transplant recipients have a reduced intravascular volume as a result of insufficient correction of intraoperative bleeding, ongoing postoperative hemorrhage and/or fluid shifts through third spacing. Hypovolemia should be corrected using volume resuscitation. In contrast to nontransplant critical care patients, liver transplant recipients may benefit more from blood transfusions and albumin [28]. The osmotic effect of blood and colloids promotes the shift of fluids from the extravascular space into the circulation, thereby improving organ perfusion while reducing graft congestion. Attention should be given to potassium, calcium, magnesium, phosphate, and glucose levels. Potassium may be elevated because of poor renal function, residual reperfusion effect, or immunosuppressive medications. Diuretics may be required to remove excess fluid acquired intraoperatively, but may result in hypokalemia and may not be effective in patients with acute kidney injury or for those with a history of hepatorenal syndrome. Magnesium levels should be kept above 2 mg per dL to prevent seizures, particularly in the presence of tacrolimus, which may lower the seizure threshold. Normal phosphate levels are needed for proper support of the
respiratory and alimentary tracts. Patients with a partial graft, such as LD recipients, often have low phosphate levels. Marked hyperglycemia may be seen secondary to steroids and should be treated with an insulin drip. Hypoglycemia is often an indication of poor hepatic function.

Nasogastric suction can usually be discontinued during the first postoperative day; patients with a choledochojejunostomy may need more time. Some form of prophylaxis for gastrointestinal (GI) bleeding should be maintained, because the physiologic stress after a liver transplant may lead to gastric erosions and ulcerations. The GI tract can be used for nutrition early on after liver transplant, often by the second postoperative day. Patients with ESLD are frequently protein malnourished; hence, there should be a low threshold for placing a Dobbhoff tube for supplemental enteral nutrition.

As soon as the patient enters the ICU, prevention, prophylaxis, and close monitoring for possible infections should begin. Given the magnitude of the operation, the often poor pretransplant medical status, and the need for immunosuppression, it is not surprising that more than 50% of liver recipients develop some type of infection. Close attention must be given to all invasive monitoring lines, which should be removed or changed every 5 to 7 days. Aggressive clearance of respiratory secretions is needed, because the lung is a common site of postoperative infection.

Graft Function and Immunosuppression

A crucial aspect of postoperative care is the repeated evaluation of graft function, which in fact begins intraoperatively, soon after the liver is reperfused. Signs of hepatic function include good texture and color of the graft, evidence of bile production, and restoration of hemodynamic stability. Once the patient arrives in the ICU, evaluation of hepatic function is continued on the basis of clinical signs and laboratory values. The patient who rapidly awakens from anesthesia and whose mental status progressively improves likely has a well-functioning graft. Laboratory values that corroborate good function include normalization of the coagulation profile, resolution of hypoglycemia, and clearance of serum lactate. Bilirubin levels may rise for a few days before trending down. Hemolysis of transfused and recycled blood, and ischemia–reperfusion injury may lead to postoperative hyperbilirubinemia in the presence of a functioning graft. Adequate urine production and good output of bile through the biliary tube (if present) are also indicators of good graft function. Serum transaminase levels will usually rise during
the first 48 to 72 hours following transplant secondary to preservation injury, and then should fall rapidly over the subsequent 24 to 48 hours. Induction immunosuppression posttransplant varies from center to center. Many programs use a triple immunosuppressive regimen based on a calcineurin inhibitor (cyclosporine or tacrolimus), antimetabolite (mycophenolate mofetil or azathioprine), and prednisone. Some centers also use antibody induction such as antilymphocyte antibody or Rituximab [29], either for all recipients or only for those with renal dysfunction. Other humanized monoclonal antibodies such as basiliximab and daclizumab are also being used as part of steroid sparing protocols or to reduce calcineurin inhibitors dose [30]. A detailed discussion of immunosuppression for transplant recipients can be found in Chapter 63.
POSTTRANSPLANT SURGICAL COMPLICATIONS

Posttransplant surgical complications are common, given the magnitude of the surgical procedure. Surgical complications related directly to the operation include postoperative hemorrhage, problems with any of the anastomoses (five vascular and one biliary), and wound complications.

Biliary Complications

Biliary complications are considered the technical “Achilles heel” of liver transplantation because of their morbidity and frequent occurrence. They include leakage, anastomotic strictures, nonanastomotic strictures, and ampullary dysfunction. In early reports, morbidity rates of up to 50% and related mortality rates of up to 25% to 30% were reported [31,32]. Recent improvements in organ selection, preservation, immunosuppression, and standardization of the methods of biliary reconstruction have all contributed to reduce the incidence of these complications. A recent meta-analysis showed that the overall incidence of biliary stricture is 13% (12% among deceased donor liver transplant (DDLT) recipients and 19% among LDLT recipients), and the overall incidence of biliary leakage is 8.2% (7.8% among DDLT and 9.5% among LDLT). The main risk factors for biliary complications include: small size of bile ducts, hepatic artery thrombosis, older donor age, prolonged ischemic times, and immunologic response (e.g., ABO incompatibility) [33]. The incidence of strictures in DCD transplants is particularly high (20% to 40% compared with 5% in grafts from brain-dead donors), possibly owing to significant ischemic damage to the biliary ducts before transplantation [34–36].

The management of biliary complications consists of: (1) endoscopic retrograde cholangiogram (ERCP) stenting, (2) percutaneous transhepatic biliary drainage (PTBD), (3) surgical revision, and (4) retransplantation. An endoscopic strategy is the first choice for biliary complications; treatment of biliary stricture with endoscopic modalities has a success rate of 57% [33].

Biliary Leaks

Biliary leaks typically occur early and are diagnosed by the presence of a biliary fistula or on a routine cholangiography. Increased inflammatory markers or fever might occur in the case of a biloma. The majority of bile leaks are seen either in the first month after liver transplant or after T-
tube removal. Late onset of bile leaks up to 6 months after transplant occasionally occurs. Risk factors for biliary leak include small size of bile ducts, discrepancy between donor and recipient ducts size, ischemic injury, and devascularization of the bile duct.

T-tube removal is a common cause of biliary leak and is reported to occur in 5% to 33% of cases [33]. Because of this concern, many transplant centers have stopped using T-tubes, although this change in practice has not been demonstrated to decrease the incidence of biliary leakage (4.7% vs. 6.3% with and without a T-tube, respectively) [33]. The management of biliary leaks varies according to the location and the severity. Conservative treatment can be attempted in selected cases when there is a small leak at the cut surface of split-liver grafts or grafts from LDs. Most biliary leaks can be treated by ERCP papillotomy and biliary stenting. In some cases, a primary surgical revision is indicated, particularly with early leaks (<1 to 2 weeks after liver transplant), large defects, or if bile duct necrosis is suspected. Surgical intervention is also indicated after failure of endoscopic therapy. Duct-to-duct repairs are not always feasible and a bilioenteric anastomosis is often required, especially in the case of periductal infection and/or bile duct necrosis [37].

Biliary Strictures

Biliary strictures can be anastomotic and nonanastomotic. Anastomotic strictures are much more common and are associated with technical failure. Biliary stenoses often result in jaundice, increased cholestatic enzymes, and fever. Ultrasound examination is less sensitive after liver transplantation, since severe dilatation of the intrahepatic bile ducts is absent in >60% of patients with anastomotic stenosis, whereas an ERCP is able to detect the cause of biliary obstruction in 95% and the site of bile leaks in 90% of cases [37]. The use of a T-tube to prevent anastomotic biliary strictures is controversial. However, a recent meta-analysis indicated that the incidence of biliary stricture was 9.7% with a T-tube and 12.5% without a T-tube [33].

Nonanastomotic strictures, also called ischemic-type biliary lesions (ITBL), or ischemic cholangiopathy, are the most troublesome biliary complication after liver transplant. ITBL is a radiologic diagnosis, characterized by intrahepatic strictures and dilatations on a cholangiogram, in the absence of hepatic artery thrombosis. The exact mechanisms are not known, but are most likely multifactorial [38,39]. The risk of ischemic cholangiopathy in grafts from DCD donors is 10 times higher than for brain-dead donors [36]. Although the risk of ITBL is directly correlated with the degree of ischemia, currently there is no way to predict which grafts will display ITBL, and no pharmacologic
approaches to prevent the development of ITBL. Available therapeutic approaches (endoscopic dilation/stenting, hepatico-jejuno anastomosis, liver resection, or retransplantation) are performed only when complications are already present. Eventually, up to 50% of patients with ITBL will die or require retransplantation [40].

The treatment of anastomotic stenosis is easier and typically achieved by ERCP repetitive balloon dilatation (every 2 to 3 months) and stenting. Severe and long anastomotic strictures are usually not amenable to endoscopic treatment, requiring surgical correction instead. For patients with bilioenteric anastomotic strictures, balloon dilatation is performed percutaneously (PTC).

ERCP and balloon dilation with or without stenting is the first choice of treatment for biliary stricture in the majority of centers (58%) and is indicated for 83% of patients. The success rate is approximately 57%.

Sphincter of Oddi Dysfunction/Papillary Stenosis

Outflow obstruction at the papillary region occurs in 2% to 7% of patients after liver transplantation and is thought to be associated with manipulation, denervation of the recipient bile duct, and inflammation or scarring of the sphincter of Oddi [41]. Clinical manifestations include increased cholestatic parameters and biliary dilatation. Endoscopic sphincterotomy is the treatment of choice and is effective in the vast majority of patients [42,43].

Vascular Complications

Vascular complications following liver transplantation include bleeding, thromboembolic events, and anastomotic failures (stenosis and thrombosis). Patients with ESLD are concurrently coagulopathic, hypercoagulable, and hyperfibrinolitic [44].

Bleeding

Despite advances in surgical technique and anesthetic management, extensive bleeding is still very common during and after liver transplantation. Bleeding negatively affects outcomes and the cost-effectiveness of liver transplantation [45–48]. Because of changes in procoagulant and anticoagulant pathways with cirrhosis, cirrhotic patients are at increased risk both of bleeding and of thromboembolic events. The most common source of bleeding after liver transplantation is
from the vascular anastomosis, but it can also arise from varices, the retroperitoneum, or the liver anastomoses. The incidence of posttransplantation abdominal bleeding, defined as any hemorrhage requiring radiologic intervention or laparotomy within the first month, is 9%, occurring at a mean of 6.1 days (range, 1 to 21 days) posttransplantation. Active bleeding is controlled by endovascular interventional techniques for 39%, by surgical ligation or vascular reconstruction for 46%, or by sequential combinations of endovascular intervention and surgery for 15% [49]. Important risk factors for bleeding include SLT, retransplantation, previous abdominal operations, severe portal hypertension, and thrombocytopenia. The risk of bleeding can be minimized by meticulous surgical dissection and bleeding control. The use of procoagulants remains controversial [50–52].

**Thromboembolic Events**

Despite prolonged coagulation times and thrombocytopenia associated with ESLD, formation of thrombi in the circulation occurs more frequently during liver transplantation than during any other type of major surgery. For a long time, there has been a dogma that cirrhosis is associated with bleeding tendency. Recent literature has challenged this dogma, showing that the coagulation system of cirrhotic patients is dysfunctional and also associated with hypercoagulability tendency [53–55]. The incidence of deep vein thrombosis (DVT) or pulmonary embolism (PE) in cirrhotic patients is 0.5%, despite 21% of patients receiving some form of DVT prophylaxis [55]. In ESLD, the low number of platelets and reduced synthesis of procoagulant factors are compensated by deficient hepatic clearance of activated procoagulants and reduced hepatic synthesis of anticoagulant proteins (protein S and C, antithrombin III, heparin cofactor II, and α2-macroglobulin), low levels of plasminogen, and elevated levels of von Willebrand factor and factor VIII [44,53,55]. In addition to the inherent hypercoagulability associated with ESLD, thromboembolism is more common during liver transplantation owing to surgical factors associated with this procedure, including the excessive activation of the coagulation system secondary to injury to a large capillary bed during hepatectomy, venous stasis during clamping of the portal vein and IVC, ischemic injury to the intestines, release of coagulation activators from the graft, and massive blood transfusion or administration of blood products [56]. Other factors that may contribute to thromboembolic complications include concomitant cancer (HCC), venovenous bypass, and use of vascular catheters [44]. The overall incidence of massive embolism associated with liver transplantation
ranges from 1.5% to 6.2% [44]. Although the estimated incidence of significant pulmonary embolism (PE) or intracardiac thrombosis among liver transplant recipients is low, these complications are potentially fatal, and therefore of great clinical relevance [44,56]. Thromboembolic events can occur during any phase of the transplantation (37% during reperfusion vs. 30% pre-anhepatic vs. 33% anhepatic) [57].

**Vascular Anastomosis Failures**

Although bleeding, stenosis, and thrombosis can arise at any of the vascular anastomoses, hepatic artery thrombosis (HAT) and portal vein thrombosis (PVT) are the most common.

**HAT.** The consequences of HAT are often life threatening, causing interruption of the graft blood supply, leading to early graft loss, long-term dysfunction, or patient death. Early HAT (within the first 3 weeks) commonly causes graft failure. Even if the graft is not lost, there will be long-term graft dysfunction. The biliary ducts are exclusively supplied by arterial blood [58], and interruption of arterial blood leads to ischemic cholangiopathy, which leads to biliary strictures, abscesses, biliary cast formation, and potentially sepsis [36]. HAT is reported to complicate 4% to 15% of OLTs and is generally more frequent after pediatric liver transplantation and LD liver transplantation [59].

Factors associated with HAT include small diameter (pediatric and LD graft), dissection of the hepatic arterial wall, anastomotic technical failures (leading to kinking, stenosis, or intima exposure), atherosclerosis (older donor age), and celiac stenosis or compression by the median arcuate ligament. Aberrant donor or recipient arterial anatomy, complex backtable arterial reconstruction of the allograft, and nonsurgical causes, such as transarterial chemoembolization, and high-resistance microvascular arterial outflow caused by severe ischemia–reperfusion injury, CMV infection, hypotension, hypercoagulable disorder, rejection are also important considerations [59–63].

Treatment of these complications has traditionally involved reexploration, surgical thrombectomy, and anastomotic revision. Failure of anastomotic revision usually requires retransplantation as a life-saving procedure. Early HAT should be treated with surgical exploration and thrombectomy. More recently, catheter-based and medical anticoagulant or thrombolytic interventions are available, but the results are inferior. However, up to 50% graft salvage rates using catheter-based treatment of HAT have been reported [64]. A single center experience with 4,200 liver transplants showed that graft salvage after early HAT requiring surgical revision, thrombectomy, and re-anastomosis was only 10.5%. Among all patients experiencing HAT, retransplantation was required in 75% of patients [59].
PVT. This complicates 3% to 7% of liver transplantations and, similar to HAT, significantly reduces both graft and patient survival [65,66]. Factors associated with posttransplant PVT include technical issues, preexisting PVT requiring thromboendovenectomy at the time of transplantation, small portal vein size (<5 mm), previous splenectomy, and the use of venous conduits for portal vein reconstruction. Presentation of PVT can include portal hypertension with gastrointestinal bleeding, ascites, elevated transaminases, and acute graft failure [59,67,68]. PVT occurs early for 65% of patients, and late for 35% [59]. Retransplantation for PVT is not always technically possible because it requires patent mesenteric graft inflow to provide hepatotrophic factors to the graft. In patients with extensive and organized PVT, this is not always possible, even with construction of a venous conduit [59,69,70].

Wound Complications

Wound complications are common following liver transplantation and may contribute to significant morbidity in the liver transplant recipient. Wound complications include infections and hematomas. Conventional risk factors for wound infections are all present in liver transplant recipients, including longer operative times, contamination with bowel or biliary contents, need for transfusion of blood products, poor nutritional status prior to transplantation, and steroid administration for immunosuppression to prevent rejection. Wound infections typically develop after the first week following liver transplantation, often presenting with fever, chills, erythema, and purulent drainage from the wound. Given the presence of immunosuppression, signs and symptoms of infection may be subtle, with the absence of typical features of inflammation. Management includes opening the wound to allow appropriate drainage of collections, frequent dressing changes, and allowing healing by secondary intention. Intravenous antibiotics may be necessary in the presence of significant cellulitis, deeper involvement, or systemic symptoms. Complicated skin and soft tissue infections, including necrotizing fasciitis, have been reported and require rapid, aggressive debridement together with appropriate selection of intravenous antibiotics.
Medical complications following liver transplantation are quite common, considering the comorbidities and often poor functional status of transplant candidates at the time of transplantation, together with the impact of significant immunosuppression. Medical complications in the early posttransplant period may involve almost any organ system (Table 58.3).

### TABLE 58.3 Posttransplant Medical Complications

</table>
### Pulmonary complications

**Infectious**
- Pneumonia (ventilator associated and/or healthcare-associated)

**Noninfectious**
- Fluid overload/pulmonary edema
- Decreased respiratory drive (sedatives, narcotics), atelectasis
- Complications associated with mechanical ventilation
  - ARDS
  - Phrenic nerve injury
  - Persistent HPS

### Renal complications

- Hepatorenal syndrome
- Acute tubular necrosis (secondary to hemodynamic compromise during surgery)
- CNI toxicity
- Sepsis, multiorgan dysfunction
- Drug-related nephrotoxicity owing to drugs other than CNIs

### Gastrointestinal complications

**Technical complications**
- Upper GI bleeding
  - Peptic ulcer disease
  - Bleeding from esophageal varices
  - Stress gastritis
  - Hemobilia after liver biopsy
  - Bleeding from Roux-en-Y anastomosis

**Lower GI bleeding**
- Colitis (cytomegalovirus, Clostridium difficile)
- Noninfectious ulcers (steroids)
- Bowel perforation or unrecognized injury to the bowel wall during transplantation

### Infectious complications (vary depending upon period posttransplant) [86]

- First 30 d posttransplant
Nosocomial infections (bacterial and fungal)
Wound infections, including superficial, deep, and organ space infections
Urinary tract infections
Pneumonia
Biliary tract infections including infected bilomas
Sepsis
Invasive fungal infections (Candida spp.)
Previously undiagnosed pretransplant infections
C. difficile colitis
Donor-derived infections (LCMV, rabies, West Nile Virus, Trypanosoma cruzi, HIV)

Between 1 and 6 mo posttransplant
(incidence varies depending on use of prophylaxis)
Biliary tract complications (infected bilomas, cholangitis, hepatic abscess)
Reactivation of latent viral infections (CMV, HBV, HCV, HSV, VZV)
Reactivation or acquisition of opportunistic infections (including fungal pathogens)
Community-acquired infections (including respiratory viral infections)
C. difficile colitis
Reactivation of latent infections (tuberculosis, strongyloides, schistosomiasis)

Later than 6 mo posttransplant
Community-acquired infections
Late-onset viral infections
Reactivation or acquisition of opportunistic infections (including fungal pathogens)

ARDS, acute respiratory distress syndrome; CNI, Calcineurin inhibitor; CNS, central nervous system; CPM, central pontine myelinolysis; CVA, cerebrovascular accidents; HPS, hepatopulmonary syndrome; PRS, postreperfusion syndrome
Nontechnical Graft Dysfunction

In addition to the surgical complications listed earlier, hepatic graft dysfunction may occur early following transplant, unrelated to technical factors. Causes of nontechnical liver dysfunction after transplant include primary nonfunction (PNF) or primary dysfunction (PDF) of the graft, acute rejection, and infection.

Primary Nonfunction and Primary Dysfunction

Hepatic PNF/PDF is one of the most serious complications in the immediate postoperative period, and is defined as a severe form of reperfusion injury that results in irreversible graft failure without underlying surgical complication or rejection [71]. Early detection is key to improving outcomes. PNF is the most common reason for early retransplantation, occurring in up to 5.8% of DDLTs, and conferring a mortality rate of approximately 80% in the absence of retransplantation. Unrecognized PNF may result in recipient death within a week of transplantation. Several factors have been described in association with PNF, including donor gender (female donors), advanced donor age (>50 years), donor hospital length of stay in the ICU before organ procurement (>3 days), macrosteatosis (>30%), prolonged cold ischemia time (CIT) (>12 hours), DCD donor status, the duration in the operating room, and retransplantation [72]. PNF should be considered in recipients who have signs of continued poor hepatic function after admission to the ICU, including persistent hemodynamic instability, worsening acidosis, persistent coagulopathy, poor bile production, worsening renal function, persistent hypoglycemia, or persistent altered mental status. There is no effective medical treatment for PNF other than supportive care; ultimately, retransplantation may be required for survival. Outcomes are typically better if retransplantation is performed as early as possible, before the development of significant multiorgan dysfunction [73].

Rejection

Graft rejection affects up to 30% of liver transplant recipients at some point posttransplantation. A detailed discussion of the diagnosis and management of graft rejection is addressed in Chapter 65. Rejection typically manifests as elevation of serum bilirubin and/or transaminase levels, occasionally with mild fever and malaise. The differential diagnosis of rejection includes vascular thrombosis, bile leaks, and underlying infection. Biopsy is required to confirm a diagnosis of rejection. Mild episodes may be managed by increasing the baseline level of immunosuppression, whereas moderate or severe rejection episodes
usually require treatment with a pulse of high-dose intravenous corticosteroids.

**Neurologic Complications**

Neurologic complications are relatively common posttransplant, affecting 15% to 30% of liver transplant recipients. Neurologic issues may develop at any time in the posttransplant period, and include alterations in level of consciousness, seizures, cerebrovascular accidents, central nervous system (CNS) infections, and central pontine myelinolysis (CPM). Pretransplant conditions, such as hepatic encephalopathy, sepsis, multiorgan failure, and substance abuse, may also have an impact on posttransplant recovery [74].

Alterations of the level of consciousness may result from medications administered for pain control or sedation, with reduced clearance due to impaired liver and/or renal function. Immunosuppressants may also contribute, particularly the calcineurin inhibitors (CNIs), such as tacrolimus and cyclosporine. The CNIs, and rarely the mTor inhibitors (sirolimus, everolimus), may cause posterior reversible encephalopathy syndrome (PRES), which develops in <1% of solid-organ transplant recipients and can manifest with headaches, alterations in consciousness, and/or seizures. Brain magnetic resonance imaging (MRI) often has typical findings, specifically, increased T2-signal in the posterior white matter. PRES most commonly develops in the first 2 months after transplant and is managed by switching immunosuppressive medications and providing supportive care [75].

Metabolic encephalopathy may persist following transplantation owing to primary graft dysfunction or nonfunction (PDF/PNF), pretransplant metabolic derangements that are slow to resolve, medications (as described above), CNS infections, evolving sepsis, or uremia due to renal failure. Significant perioperative hypotension may cause hypoxic–ischemic encephalopathy, or even ischemic cerebrovascular accidents (CVAs). The latter are not common after liver transplantation, occurring in 2% to 4% of transplant recipients. Older recipients or those with diabetes mellitus may be at increased risk for CVAs [74].

Central pontine myelinolysis (CPM) or extrapontine myelinolysis (EPM) may develop among 1% to 2% of liver transplant recipients, in the setting of significant fluid shifts and excessively rapid correction of hyponatremia [74]. Factors that may confer increased risk include pretransplant hyponatremia or severe hepatic dysfunction prior to transplant. Manifestations include decreased levels of consciousness and spasticity. MRI of the brain may reveal characteristic T2 hyperintensity in the central pons.

Acute changes in mental status or development of focal neurologic
findings should prompt urgent imaging to rule out a CNS hemorrhage or infection. Coagulopathy due to hepatic dysfunction pretransplantation may occasionally result in intracranial bleeding. Immunosuppressive medications confer an increased risk for meningitis, meningoencephalitis, or brain abscess. Early posttransplant, donor-derived infections must be considered (including lymphocytic choriomeningitis, a viral infection transmitted from rodents), as well as reactivation of infections in the recipient, including viruses such as herpes simplex virus (HSV), cytomegalovirus (CMV), and varicella zoster virus (VZV). The risk of CNS infection increases after the first month following transplantation, with etiologies reflecting both new exposures and reactivation of latent infections acquired via travel or endemic exposures. Potential etiologies include cryptococcal meningitis or other endemic mycoses, nocardiosis, and listeriosis. A detailed discussion of infections following transplantation is included below and in Chapter 65.

Posttransplant seizures have variable etiologies, depending on the timing of onset following transplantation. In the first few weeks posttransplant, seizures are typically the result of metabolic derangements or adverse effects from medications. However, it is crucial to also consider and rule out other causes, including a cerebrovascular accident, CNS bleeding, or infectious processes (meningitis, encephalitis, or an intracranial abscess). CNS imaging should be obtained routinely in patients with new-onset seizures, to rule out a mass lesion or bleed.

Cardiovascular Complications

Cardiovascular (CV) complications may develop among liver recipients with previously diagnosed cardiac disease, but may also occur among those not known to have preexisting cardiac comorbidities. As the mean age of liver transplant recipients increases, strategies to reduce the risk of cardiac events and optimization of medical management prior to liver transplant are essential, in order to minimize the risk of CV complications in the posttransplantation period. The hemodynamic and metabolic profiles associated with liver disease differ from those seen among other transplant candidates, and alter the risk and manifestations of CV events following transplantation. These differences include lower systemic blood pressure, lower peripheral vascular resistance, lower serum cholesterol levels, and relatively less atherosclerotic vascular disease [76]. Despite this lowered overall risk, CV events are reported to be a significant cause of morbidity and mortality among liver transplant recipients, contributing to 12% to 16% of deaths posttransplantation in...
the United States. CV-attributable mortality is usually late onset, beyond the first year posttransplantation [77].

The period after liver reperfusion is a time when the majority of intraoperative cardiac complications develop. Transient hypotension during liver reperfusion may cause a postreperfusion syndrome (PRS), which is defined as a decrease in mean arterial pressure (MAP) of at least 30% for 1 minute, during the first 5 minutes following reperfusion. The drop in MAP is accompanied by a decrease in myocardial contractility (decreased heart rate, increased CVP and PCWP) and a drop in SVR. PRS occurs in up to 30% of liver transplant recipients, and is likely because of multiple factors, including hyperkalemia and acidosis. In addition, factors released from the ischemic graft upon reperfusion, may effectively depress myocardial function. Although this phenomenon is usually transient, resolving within 5 minutes, it may have a significant and lasting impact, particularly for patients with preexisting cardiac disease. The bradycardia and hypotension may lead to cardiac arrest and malignant cardiac arrhythmias, such as ventricular tachycardia or fibrillation.

Postoperative myocardial ischemia may occur among as many as 13% of liver transplant recipients. To minimize the risk for cardiac complications, liver transplantation candidates with previously diagnosed coronary artery disease (CAD), or those with risk factors for CAD identified during the pretransplant evaluation, should be evaluated by a cardiologist prior to transplantation, so as to maximize medical management of cardiovascular risk factors. Pharmacologic cardiac stress testing is now the standard of care in the pretransplant evaluation of liver transplantation candidates who have risk factors for CAD. Transplantation candidates with positive results on pharmacologic stress testing should be referred to a cardiologist for consideration of diagnostic coronary angiography, so as to determine whether further intervention is indicated prior to transplantation.

Pulmonary Complications

Pulmonary complications in the setting of liver transplantation are quite common, reported in 40% to 47% of liver transplant recipients, and may be attributable to both infectious and noninfectious etiologies [78]. Noninfectious causes predominate during the first week posttransplant, owing to fluid shifts, fluid overload, decreased respiratory drive due to the use of sedative and narcotic medications to manage pain, and as a result of complications associated with mechanical ventilation. With increasing time following the transplant procedure, infectious pulmonary complications become more prevalent. In one study, causes of pulmonary infiltrates included pulmonary edema in 40%, pneumonia in 38%,
atelectasis in 10%, and ARDS in 8% [79]. In this study, 87% of cases of pneumonia identified in the ICU setting occurred among patients who had been mechanically ventilated.

The majority of liver transplant recipients are extubated within the first 48 hours following transplantation. Recipients with prolonged hospitalizations prior to transplantation or preexisting pulmonary disease, those who are significantly malnourished at the time of transplantation, and those with significant infectious or hepatic complications posttransplant may require a prolonged course of mechanical ventilation following liver transplantation. A recent review of early respiratory complications following liver transplantation highlighted the most common preoperative risk factors for post–liver transplant pulmonary complications, including recipient age, female gender, history of tobacco use, severity of liver dysfunction, presence of pretransplantation hepatic encephalopathy, mental status changes, acute renal failure, preexisting pulmonary disease, preoperative ventilatory support, and pretransplant diabetes mellitus [78]. Preoperative mechanical ventilation is a significant risk factor owing in part to the increased risk of lower respiratory tract infection, and reflective of the severity of liver disease in the transplantation candidate, in the immediate pretransplantation period. Intraoperative risk factors for pulmonary complications are primarily related to fluid shifts and fluid overload related to resuscitation during surgery, and the abdominal surgical procedure itself, decreasing respiratory compliance and making extubation more difficult [78].

Postoperative factors associated with an increased risk for complications include the residual effects of anesthetics used during the transplantation, decreased hepatic and renal clearance of narcotic medications used to control pain, and continued fluid overload. Persistent large volume abdominal ascites may contribute to atelectasis and a 50% to 60% decrease in vital capacity. This may result in difficulty with weaning from ventilatory support and extubation [80]. While phrenic nerve recovery does occur, it can often be a prolonged process. Hepatic dysfunction, the need for reoperation/abdominal exploration for various issues, and continued poor nutritional status can all lead to a delay in weaning from mechanical ventilation.

Posttransplant pneumonia, classified as either healthcare associated and/or ventilator associated, may develop in up to 38% of liver transplant recipients. The incidence is highest between 7 and 10 days after transplantation, declining thereafter, unless additional risk factors remain. These include prolonged ventilatory support, poor nutritional status, severity of liver disease, pretransplant hospitalization, and medical comorbidities such as diabetes mellitus and preexisting pulmonary disease. Each of these factors will contribute to an increased
risk of pneumonia in the posttransplantation period. If a healthcare-associated pneumonia is suspected, it is imperative to identify the causative organism, in order to tailor antimicrobial coverage appropriately. Liver transplantation candidates may be colonized with resistant nosocomial gram-negative organisms, by virtue of the frequency of their interactions with the healthcare environment, exposure to antimicrobial agents, the duration of pretransplantation hospitalization, as well as the presence of prolonged mechanical ventilatory support. Adequate sputum samples should be obtained and sent for Gram stain and culture to identify bacterial pathogens. Bronchoscopy with bronchoalveolar lavage may be necessary in order to identify a causative organism. Empiric antimicrobials should be chosen on the basis of the antibiogram of the local ICU, because the microbiology and sensitivity patterns can vary significantly between different hospitals and even between different units within a hospital.

Hepatopulmonary syndrome (HPS) is characterized by severe hypoxemia, significantly increased alveolar arterial oxygen gradient, and intrapulmonary vascular dilatations in the setting of chronic liver disease. HPS may be reversible in up to 90% of patients after liver transplantation, usually within a year following transplantation [81].

Renal Complications

The majority of liver transplantation recipients have some degree of renal dysfunction in the posttransplantation period. Renal dysfunction may be acute or chronic, with up to 10% of liver transplantation recipients requiring dialysis posttransplantation. Abnormalities may be attributable to complications from the surgical procedure itself or from the effects of transplant immunosuppression, specifically, the CNIs. Renal dysfunction may also be present prior to transplantation, for example, owing to preexisting hepatorenal syndrome, and may persist or progress after transplantation. Renal complications posttransplantation, whether new or progressive, increase transplantation-associated morbidity and may have a significant negative impact on both patient and graft survival [82].

Preexisting kidney disease owing to HRS or ATN may improve after restoration of normal hepatic function, but they may also confer a greater risk for the development of chronic kidney disease (CKD) after transplantation. Factors associated with a greater risk of progression to CKD include need for renal replacement therapy (RRT) before transplant, hemodynamic compromise during the transplant surgery, and CNI toxicity posttransplantation. Sepsis and multiorgan dysfunction during
the posttransplant setting may also contribute to an increased risk for progressive renal disease. Drug-related nephrotoxicity is most commonly attributable to the CNIs (cyclosporine or tacrolimus) but may also result from other agents, including antimicrobials such as vancomycin, aminoglycosides, and amphotericin B. Individuals who were dependent on dialysis before transplant are unlikely to regain significant renal function after liver transplantation, and may be candidates for a combined liver–kidney transplant.

Management of renal dysfunction following liver transplantation, with the goal of preserving residual renal function, can be achieved with appropriate hemodynamic monitoring, maintenance of normal blood pressure through the use of resuscitation with fluids and/or blood products as indicated, and administration of antihypertensive agents as required. In addition, the use of nephrotoxic agents should be minimized.

Gastrointestinal Complications

Gastrointestinal (GI) complications are common after liver transplantation, and may result from technical complications, stress related to the postsurgical state, bleeding, or infections. Upper GI bleeding following liver transplantation may result from peptic ulcer disease, persistent bleeding from esophageal varices, or stress gastritis. Diffuse gastritis secondary to surgical stress is uncommon in the current era owing to the use of routine prophylaxis with proton pump inhibitors. Peptic ulcer disease remains a potential cause of upper GI bleeding, occurring most commonly in the first month posttransplantation, perhaps related to relatively higher doses of steroids. More unusual causes of GI bleeding include hemobilia after liver biopsy (incidence of 0.03%) and bleeding from the Roux-en-Y anastomosis in those patients who required cholechochojejunostomy.

Lower GI bleeding following liver transplant is often secondary to colitis, typically owing to an infection such as CMV or Clostridium difficile. Noninfectious ulcers may also cause colonic bleeding, perhaps related to the effects of high-dose steroids used in induction therapy.

Bowel perforation is a devastating complication and is associated with a high mortality rate. The signs and symptoms that are typically associated with acute peritonitis, including high fever and severe abdominal pain, may be attenuated by the effects of immunosuppressive agents. Perforation may occur in the small or large bowel, the latter being associated with a higher mortality rate owing to the high risk of infection from heavy bacterial colonization of the large bowel. Unrecognized injury to the bowel wall during the transplant is uncommon, but when it occurs, it may later present as a perforation with peritonitis. Perforations may also be spontaneous; these occur more commonly in children, generally 1
to 2 weeks posttransplantation, and may be related to the effects of high-dose steroids. As with perforation in patients who have not undergone transplantation, early diagnosis with prompt reexploration and copious irrigation to decrease the degree of bacterial contamination is the best option.

**Infectious Complications**

Although infectious complications are common in all organ transplants, in liver transplant recipients the incidence is reported as high as 50% in some studies [86, 87]. The higher relative rates of infection in liver transplant recipients is due in part to operative factors (duration and type of surgery), the risk of biliary and enteric contamination during surgery, and the poor nutritional status and presence of medical comorbidities among patients with ESLD. Infectious complications following transplantation in general are discussed in detail in Chapter 65.

Despite the relatively higher risk of infection for liver transplant recipients, mortality rates attributable to infections have improved in recent years and are now reported as low as 10% in some series [86, 87]. Reasons for the decrease include improved posttransplant critical care, reduced use of venovenous bypass, thoughtful selection of appropriate antimicrobials, and careful titration of immunosuppression. Even with these improvements, infectious complications continue to impact patient and graft survival, hospital length of stay, and cost of care following transplantation.

Pretransplant identification of risk factors for infectious diseases, and modification of these risks when possible, can have a positive impact on outcomes. Effective prophylaxis to prevent reactivation or transmission of infection and a prompt response to the diagnosis and treatment of infections when they occur is crucial to decrease posttransplant morbidity and mortality related to infectious diseases.

**Pretransplant Evaluation**

The purpose of the pretransplant evaluation is to determine the risk for or presence of active or latent infectious diseases. Pretransplant serologic testing includes laboratory assessment of prior exposure to cytomegalovirus (CMV), Epstein–Barr virus (EBV), varicella zoster virus (VZV), syphilis, human immunodeficiency virus (HIV), and hepatitis viruses (A, B, and C). Latent infections that may reactivate during transplantation immunosuppression must be identified and are most optimally treated before transplantation. Pretransplant infectious disease screening should be tailored, with consideration of the travel history of the transplant candidate, and may include assessment for prior exposure
to tuberculosis, strongyloides, and schistosomiasis [87].

Transplantation in the setting of untreated latent tuberculosis infection (LTBI) is reasonable; treatment of LTBI may be delayed until after transplantation if significant liver dysfunction precludes administration of medications for the treatment of LTBI or if delaying transplantation until LTBI treatment can be completed carries too high a risk of mortality for the liver transplant candidate. Vaccines for preventable infections should be administered at the time of the pretransplant evaluation, in accordance with current guidelines [87]. Active infections that require treatment before transplantation or that might delay transplantation should optimally be identified and addressed before candidate listing. Patients with ESLD have increased susceptibility to infectious complications even before transplantation, by virtue of their relative immune compromise due to cirrhosis and splenomegaly, when present. Infections that are frequently identified in patients with ESLD include spontaneous bacterial peritonitis, cholangitis, recurrent sinupulmonary infections, and more rarely, cryptococcal infection (cryptococcemia and meningitis). In cases where delaying transplant may increase the risk of mortality, it may in some cases be prudent to begin treatment of the underlying infection and then to proceed with transplantation while continuing antimicrobial treatment of the infection. Decisions such as this should be individualized, with a collaborative team approach involving the transplant team, the critical care team, and experts in infectious disease care of transplant candidates and recipients.

Perioperative Prevention of Infection

Perioperative antibiotics with activity against biliary tract pathogens are administered before surgical incision and are typically continued for up to 24 hours following transplant. The choice of agent varies by center but may include ceftriaxone, ampicillin-sulbactam, or piperacillin-tazobactam. Perioperative prophylactic strategies should be guided by the local flora that are commonly identified within the hospital, and protocols should be developed in consultation with infection control experts at the transplant center, recognizing the increasing complexity of these decisions in the setting of emerging multidrug-resistant pathogens [87]. Fluconazole may be added for 28 days to prevent the development of invasive fungal infection (IFI) for patients at increased risk for this complication [83]. Risk factors for IFI include preexisting renal dysfunction, duration of operative procedure, transfusion of significant volume of blood products during the transplantation procedure,
retransplantation, abdominal or intrathoracic reoperations, cytomegalovirus infection, Roux-en-Y hepaticojejunostomy, and colonization with yeast at the time of transplantation [83,84].

Transplant recipients typically receive trimethoprim–sulfamethoxazole for 1 year or more to prevent infection due to *Pneumocystis jiroveci* (patients with sulfa allergy may receive dapsone or atovaquone as alternatives) and either valganciclovir (if donor or recipient is CMV IgG positive) or acyclovir (if both donor and recipient are CMV IgG negative) to prevent infection due to herpesviruses. Nystatin is provided for a short period, usually 1 to 3 months posttransplant, for those recipients who do not meet criteria for systemic antifungal prophylaxis.

**Postoperative Assessment for Infection**

The development of fever following liver transplantation should be thoroughly investigated to rule out infection, given the morbidity and mortality associated with a delay in treatment. The evaluation includes a comprehensive physical examination, with particular attention to the surgical wound, entry sites for indwelling catheters, and respiratory status. Liver transplant recipients, as with all solid-organ transplant recipients, develop typical postoperative complications such as line infections, pneumonias, urinary tract infections, and wound infections. The most common infections following liver transplantation are pulmonary infections, superficial incisional wound infections, and deeper, organ space intra-abdominal infections [85, 87].

As part of the initial evaluation, cultures should be obtained from blood, urine, sputum, ascitic fluid when present, and any other fluid collections identified through the clinical exam, laboratory testing, or imaging. A good-quality chest radiograph should be obtained in order to rule out a pulmonary source of the fever, understanding that plain radiography may not be sensitive enough to reveal an etiology in some patients and that chest CT may be required to more adequately assess any infiltrates present on a plain chest radiograph.

If physical examination combined with initial laboratory and radiographic evaluation does not reveal a source of infection, abdominal imaging with a CT scan may be necessary to identify fluid collections that could be a source of infection. If present, fluid collections should be sampled for Gram stain and culture. Initiation of broad-spectrum empiric antimicrobials should be considered if the recipient is febrile or has hemodynamic instability, even before a source is identified, because of the significant risk of rapid clinical decline in the setting of infection in transplant recipients. Reasonable initial coverage should include broad-spectrum antimicrobials that have activity against biliary pathogens. Coverage of multidrug-resistant organisms should be considered if there
is an increased prevalence of these organisms at the transplant center. Consultation with infectious diseases physicians with expertise in transplant care and infection control is recommended to determine the optimal empiric regimen.

A detailed description of infectious complications after solid-organ transplantation is provided in Chapter 65. Infectious complications following solid-organ transplantation have been categorized as occurring early (within 1 month), between 1 and 6 months after transplant, and more than 6 months posttransplant and are dependent on the “net state of immunosuppression” of the recipient [86]. This phrase, described by Fishman, Rubin, and colleagues, refers to the intensity and duration of immunosuppression, together with host factors, that may impact risk of infection at different points in time following transplant [86].

Among liver transplant recipients, bacterial and fungal organisms are the most common causes of infection during the first month following transplant and are typically related to surgical complications, initial graft function, and recipient pretransplant comorbidities. Risk factors for early posttransplant infections include increasing duration of the transplantation surgical procedure, blood transfusions in the perioperative period, retransplantation, and surgical reexploration. Following the first month after transplant, the “net state of immunosuppression” becomes an important factor contributing to the ongoing risk for infection [86]. Opportunistic pathogens, including viral, fungal, and parasitic pathogens, are more commonly seen during this period. Administration of augmented immunosuppression to treat acute rejection episodes with either bolus high-dose steroids or antilymphocyte agents will increase the risk of infection due to opportunistic pathogens.

Bacterial infections following liver transplantation are most commonly related to the surgical wound, and may be superficial, deep, or organ-space infections. The bacterial pathogens commonly associated with surgical-site infections are from a biliary or bowel source and may complicate a biliary leak. The risk of infection from a biliary source is higher with choledochojejunostomy (CDJ) than with duct-to-duct biliary anastomosis. Wound infections may present with typical signs of infection, such as increased drainage, erythema, or fluctuance, or they may be subtle, with only minimal findings (fever, elevated white blood cell count, or hemodynamic instability) due to the effects of induction immunosuppression. Patients will usually present with signs of focal intra-abdominal infection or sepsis, often with evidence of cholangitis, discrete abscesses, or peritonitis. Abdominal CT scanning may help to identify the presence of a focal collection, which should be aspirated and cultured whenever feasible.

Management of wound infections may require opening of the wound, irrigation and drainage as indicated, serial dressing changes, healing by
secondary intention, and administration of systemic antibiotics, depending on the severity and depth of the infection. Treatment of infected collections requires drainage of the collection, irrigation, and correction of biliary complications. Drainage may be open or percutaneous, depending on the size, location, and complications related to the collection. Broad-spectrum intravenous antibiotics should be chosen to cover the most likely pathogens, which include aerobic and anaerobic enteric gram-negative bacilli and gram-positive cocci. Local transplant center flora and the presence of multidrug-resistant pathogens should be considered when selecting empiric antibiotics. Antibiotic coverage can be tailored on the basis of culture results, to focus the antimicrobial treatment [87].

Liver transplant recipients have the highest incidence of fungal infection, although the incidence has been decreasing due to effective prophylactic approaches and improved perioperative techniques and care [87]. Risk factors and management have been well described elsewhere and are discussed in another chapter in this book [83, 87]. Candida species are the most commonly isolated pathogens and often develop early posttransplant, usually within the first 1 to 2 months. Opportunistic fungal infections usually occur later, as a result of a longer duration of immunosuppression or more intense/augmented immunosuppression.

Viral infections typically develop more than 1 month after transplant, as a result of the cumulative effects of immunosuppression [86]. Viral pathogens that reactivate in the setting of immunosuppression include CMV, EBV, HSV, and hepatitis viruses (B and C). Occasionally, primary infection due to these viruses can occur. Viral infections in transplant recipient result in both significant morbidity and increased cost of care. CMV is the most common viral infection diagnosed following liver transplantation. Infection with CMV is typically evident within 1 to 6 months after liver transplant and can be due to either reactivation (recipient seropositive pretransplant) or transmitted infection from the donor (donor seropositive/recipient seronegative) [87]. Manifestations of CMV infection include asymptomatic viremia or CMV disease [90]. Asymptomatic viremia may be detected through routine posttransplant surveillance. CMV disease is diagnosed by the presence of viremia together with clinical signs and symptoms such as fever, malaise, and leukopenia, with or without specific end-organ involvement. The diagnosis of tissue-invasive CMV disease requires biopsy with demonstrated presence of viral inclusions on histopathology. Tissue-invasive disease most commonly involves the liver, gut, or lungs,
although encephalitis and retinitis are rarely described in this population [87, 90]. Strategies to prevent reactivation or transmission of primary CMV infection include universal prophylaxis with valganciclovir and preemptive treatment, with close monitoring to detect viremia and initiate antiviral treatment before significant end-organ disease due to CMV develops. Both strategies are effective; the reasons for choosing one approach over another include risk of CMV infection, feasibility of preemptive monitoring, the ability of the transplant center/staff to receive laboratory test results in a timely manner, cost, and adverse effects of valganciclovir prophylaxis. For patients at high risk for primary CMV disease (donor CMV IgG positive, recipient CMV IgG negative), universal prophylaxis is most commonly chosen for a duration of 3 to 6 months after transplantation [87, 90].
CARE OF THE LIVING LIVER DONOR

Living liver donation surgery is a partial hepatectomy, involving surgical removal of up to 60% to 70% of the liver. If at any point the surgical team believes that the donor is at risk or that the segment of the donor’s liver is not appropriate for transplantation, the surgery is stopped. This happens in the United States at least 5% of the time. Following surgery, the donor is admitted to the intensive care unit for at least 1 day for observation. Live liver donors may be discharged approximately 5 to 7 days after surgery. The postoperative recovery period is from 4 to 6 weeks. Most donors return to their usual activities within 12 weeks, and may begin more demanding activities 6 months after their surgery.

Surgical Risks for LDs

Although living liver donation is highly successful, complications for the donor and the recipient may arise. The overall incidence of donor complications after LD liver donation ranges from 5% to 10%. There is also a small risk (<0.5%) of death [88,89]. Of note, mortality is higher for adult-to-adult donation (0.24% to 0.4%) compared with adult-to-child donation (0.09% to 0.2%). This is explained by the fact that adult-to-child donation usually involves removal of a smaller portion of the liver.

Adverse reactions may occur as a result of anesthesia or other medications administered at the time of surgery. Bleeding may occur postoperatively, possibly requiring blood transfusion(s). Other complications include infections (wound, urinary tract, pneumonia), blood clots in the legs, PE, gastrointestinal problems (bowel obstruction, nausea/vomiting, constipation), incisional pain, numbness around the incision, and abnormal sensation of the upper extremities. Other complications after donor surgery may include incisional problems such as hernias. The risks of DVT and PE are the same as for other major abdominal procedures. A rare but serious complication is liver failure that may require a liver transplant to correct (this occurs in about 2 transplants per 1,000 living liver donor surgeries), or death. The mortality rate of a living liver donor is 5 in 1,000.

Bile duct problems are the most worrisome complication after donor surgery. The rate of this happening across the country ranges from 5% to 15%. At our center, 5% of patients undergoing operations similar to live donor liver surgeries have had bile leaks. Bile may leak from the cut surface of the liver or from the site where the bile duct is divided. That site may later become strictured. Generally, bile leaks resolve spontaneously with simple drainage. Strictures and occasionally bile
leaks may require an ERCP and stenting. If the above measures fail, a reoperation may be required. Intra-abdominal infections developing among donors are usually related to a biliary problem.

Biliary strictures (narrowing of the large ducts that drain the liver) can also occur after live donor partial hepatectomy. These strictures confer potential long-term complications. Current data suggest that these strictures are rare and that some of them can be fixed without additional surgery. Another rare event that may happen is injury to the spleen during the surgery. If this complication occurs, the spleen may be removed.

Postoperative ICU Care

Once stability is achieved, the patient is positioned on his or her left side with right side up during the first 48 hours postoperatively whenever the patient is in bed. Jackson Pratt drains are placed intraoperatively and monitored for the presence of normal (serosanguinous) versus abnormal (bilious, bloody, purulent) drainage. The donor typically has a nasogastric tube to low continuous suction, with the duration of placement determined by the donor transplant surgeon. Worsening abdominal pain warrants a thorough abdominal assessment for possible signs of bleeding, gastric dilatation, or pleuritic symptoms. As with the transplant recipient, the donor receives medications for stress ulcer prophylaxis. In addition, anticoagulation and venodyne boots are provided for DVT prophylaxis in accordance with published guidelines.

Complications following live donor partial hepatectomy include but are not limited to acute hemorrhage (manifest as hypotension, mental status changes, decreased hematocrit, tachycardia, and increasing abdominal pain), infection (wound infection or pneumonia most commonly), gastric dilatation (often developing by postoperative day 3 or 4, and manifest as bloating with nausea), hypophosphatemia (commonly developing around postoperative days 3 to 4), CNS abnormalities, and rarely renal, hepatic, cardiac, or respiratory dysfunction.

In order to decrease the risk of complications, donors should receive continued education regarding hospital expectations throughout their inpatient stay. Donors should be instructed on the correct use of an incentive spirometer and encouraged to cough and deep-breathe frequently with a therapeutic cough pillow. The donor’s diet is advanced as his or her condition allows. The team will optimize the donor’s nutrition to meet the latter’s needs for wound healing. Donors may
typically be assisted out of bed to chair on postoperative day 1 and advanced to ambulation as tolerated.

**Expected ICU Course**

Patients are managed with isotonic crystalloid (normal saline) with close monitoring. A low CVP is preferred, to minimize intra- and postoperative bleeding. Volume expansion in the postoperative period is expected to be associated with modest declines in the Hb levels. Urine flows of 0.5 mL/kg/hr. are desired, and additional boluses and rates of 125 mL per hour are not unexpected. The postoperative INR is expected to be in the 1-to-1.5 range, and may rise to as high as 2.5 in the early postoperative period. This is managed with vitamin K in some cases. FFP transfusions are not given. The platelet count is not expected to fall significantly. Transfusion is not expected, and the hematocrit rarely falls below 25. Postoperative pain is managed with a narcotic patient-controlled analgesia (PCA) pump. Additional small intravenous doses (50 mcg fentanyl, 1 mg morphine, 0.5 mg dilaudid) of narcotic are sometimes required. Patients are treated with a first-generation cephalosporin for 24 hours beginning at the time of incision, but are generally not needed after the initial 24 hours.

**Postdonation Care**

Live liver donors are followed by the transplant program for follow-up care, including evaluations such as blood pressure, lab studies, and other routine tests. Transplant centers are required to report follow-up information on all LDs for 2 years after donation.
SUMMARY

Care of liver transplant recipients before, during, and after surgery is a significant challenge, given the comorbidities and complications associated with ESLD. These patients are typically quite debilitated and deconditioned going into transplantation, and a variety of medical and surgical complications can occur following transplantation. Despite dramatic advances in the field, liver transplantation remains a major undertaking with the possibility of complications affecting every major organ system. A systematic approach is necessary to prevent, minimize, and manage these complications. Intensive medical care in an ICU setting may be necessary even pretransplantation, particularly for patients with FHF or severely decompensated chronic liver disease. Optimizing the overall medical status of transplant candidates with chronic liver failure is essential to decrease the likelihood of postoperative problems. Immediately posttransplantation, intensive monitoring in a critical care setting by providers with experience in the care of liver transplant recipients is necessary to ensure an optimal outcome. A thorough knowledge of potential complications is required to allow for rapid diagnosis and appropriate treatment.
ACKNOWLEDGMENT

The authors would like to acknowledge the authors of previous edition, Ruy J. Cruz Jr, William D. Payne and Abhinav Humar, for their work in writing this chapter, from which the current version is adapted.
REFERENCES

Over the past three-plus decades, lung transplantation (LT) has become a successful therapeutic option for patients with end-stage pulmonary parenchymal or vascular disease. In the early era of LT, the primary complications associated with the procedure were dehiscence and impaired healing of the bronchial anastomosis, and early graft failure; these complications occurred in most patients who survived for more than 1 week. Improvements in donor and recipient selection, organ allocation and availability, and surgical techniques, the development of new immunosuppressive drugs, and better management of complications, such as primary graft dysfunction (PGD), rejection, and infections have all contributed to advancing the field (Table 59.1). Despite these advances, LT is still associated with numerous complications, often requiring intensive care management.

ECMO as bridge to lung transplantation
Considered as a viable option for end-stage pulmonary patients awaiting lung transplantation [5,9]

Improved short-term survival and decreasing waiting time for lung transplant recipients
Experienced centers now with over 90% survival at 1 y and waiting time under 4 mo [2,18]

Acute antibody-mediated rejection after lung transplantation
Establishes the role of antibodies in acute rejection and proposes criteria for diagnosis [70,72]

Description of CLAD
Defines both phenotypes of the obstructive pattern as BOS and the RAS [75,111]

BOS, bronchiolitis obliterans syndrome; CLAD, chronic lung allograft dysfunction; DCD, donation after circulatory death; RAS, restrictive allograft syndrome.

According to the 2015 report of the International Society for Heart and Lung Transplantation (ISHLT), more than 3,893 adult lung transplants were performed in 2013. The ISHLT Registry reports that the 1-year survival rate for lung transplant recipients is 80%, the 3-year rate is 65%, and the 5-year rate is 54% [1]. The median survival rate for the recent years was 5.7 years. However, there is a marked difference in survival rates according to the type of transplant procedure, with a median survival of 7.1 years for the bilateral lung transplantation (BLT) recipients compared with 4.5 years in those who underwent a single-lung transplantation (SLT) procedure. The recipients who survived to 1 year after primary transplantation had a conditional median survival of 7.9 years (9.7 years for bilateral recipients and 6.4 for single-lung recipients).

It is important to mention that there is also high variability of survival rates among different LT programs; if one examines US-specific data from the Scientific Registry of Transplant Recipients (SRTR), survival rates at 1 year are higher than 88%, with experienced centers achieving 1-year survival rates >90% and 3-year survival rates over 75%. These higher survival rates may in part reflect advances in critical care management of lung transplant recipients [2].

The most common cause of mortality is PGD for the first 30 days following transplantation, non-cytomegalovirus (CMV) infection in the 1st year following transplantation, and chronic rejection for all subsequent time intervals [1].
INDICATIONS

The most frequent indications for SLT are obstructive nonsuppurative lung disease, such as emphysema resulting from tobacco use (42% of all SLT procedures reported to the ISHLT Registry) or $\alpha_1$-antitrypsin deficiency (5%). It is also indicated for diffuse parenchymal lung diseases (39%) such as interstitial lung disease including idiopathic pulmonary fibrosis, familial pulmonary fibrosis, drug- or toxin-induced lung disease, and occupational lung disease, as well as sarcoidosis, limited scleroderma, lymphangioleiomyomatosis, eosinophilic granuloma, and other disorders resulting in end-stage fibrotic lung disease [1].

The steady increase in the overall number of lung transplants over the past 10 years has been due to a significant increase in the number of BLT procedures, now representing over 75% of the total number of LTs. The most frequent indications for BLT are suppurative pulmonary lung disease, cystic fibrosis (24%) and bronchiectasis, severe chronic obstructive pulmonary disease (COPD) resulting from tobacco use (27%), or $\alpha_1$-antitrypsin deficiency (6%) and diffuse parenchymal lung diseases (22%). In addition, more than 95% of transplants for pulmonary hypertension (PH) are BLT procedures [1].

Heart–lung transplantation (HLT) is performed at only a few transplantation centers and should be reserved for patients who cannot be treated by LT alone. The most frequent indications for HLT are Eisenmenger syndrome with a cardiac anomaly that cannot be corrected surgically and severe end-stage lung disease with concurrent severe heart disease. HLT is discussed in more detail in Chapter 60.
GUIDELINES FOR RECIPIENT SELECTION

An ISHLT consensus document recently updated the previous consensus-based guidelines (1998 and 2006) for the selection of lung transplant candidates [3]. LT should be considered for any patient with chronic, end-stage lung disease who meet all the following criteria: high (>50%) risk of death from lung disease within 2 years if LT is not performed, high (>80%) likelihood of surviving at least 90 days after transplantation, and a high (80%) likelihood of 5-year posttransplant survival from a general medical perspective provided that there is adequate graft function.

Age

The 2014 ISHLT consensus document for the selection of transplant candidates [3] suggest an age >65 years in association with low physiologic reserve as a relative contraindication regardless of procedure type, and 75 years as an absolute contraindication to LT.

Relative Contraindications

Transplantation is relatively contraindicated in patients with systemic diseases that have extrapulmonary involvement such as scleroderma, systemic lupus erythematos, polymyositis, and rheumatoid arthritis. Advanced atherosclerotic disease is also considered a relative contraindication unless this can be corrected before, or in very selected cases concurrently, with transplantation. Osteoporosis is a significant problem after LT, and preexisting symptomatic osteoporosis is also a relative contraindication.

Patients with active sites of infection are not considered to be good transplantation candidates. Treated tuberculosis and fungal disease pose a particular problem but are not contraindications for LT. Many centers will not consider performing a transplant in a patient who is chronically colonized with a resistant organism (e.g., *Burkholderia cenocepacia*, atypical mycobacterium such as *abscesses*), and it is recommended to try to eradicate these organisms in the pretransplant period and to consider each patient on an individual basis. However, if considered, these patients are candidates only for BLT procedures since the remaining colonized lung could pose a serious threat to the new graft in the case of an SLT. This issue is of particular concern in cystic fibrosis patients who are often infected with drug-resistant organisms. Both *Burkholderia cenocepacia* (specific strains) and *Burkholderia gladioli* are of concern due to poor posttransplantation outcomes [4].
As patients are now allocated lungs for transplantation according to the severity of their disease, requirements for invasive mechanical ventilation and extracorporeal life support are now more frequently seen. During this critical period, patients usually have multiple acute changes that pose a relative or absolute contraindication to transplantation, and the candidacy for this procedure should be assessed on a continuous basis [5–7]. In one small series of mechanically ventilated patients, there was a longer time on postoperative mechanical ventilation and a longer intensive care unit (ICU) stay following LT. Rates of PGD, survival, and total hospital stay were similar to those in patients undergoing LT not on mechanical ventilation [6]. Recently venovenous and/or venoarterial extracorporeal membrane oxygenation (ECMO) has been used as a bridge to transplantation for end-stage lung disease patients with good short-term function and survival rates [5,7]. In a large review of the United Network of Organ Sharing (UNOS) database of patients undergoing LT on mechanical respiratory support (586 on mechanical ventilation and 51 on ECMO as a bridge to LT), the authors found that patients on mechanical ventilation or ECMO have lower survival rates following LT compared with those not requiring support [8]. A small study of 25 patients receiving ECMO as a bridge to transplant showed that the duration of ECMO was related to mortality (which increased steadily with time on ECMO) and morbidity (ICU length of stay, days on mechanical ventilation, and hospital stay) following LT [9]. Noninvasive ventilatory support is not considered a relative contraindication to transplantation.

To be considered for transplantation, patients should have an ideal body weight of >70% or ≤130% predicted (BMI, 18 to 30 kg per m²). Those patients with poor nutritional status may be too weak to withstand the surgical procedure; those patients who are obese (BMI, 30–35 kg per m²) make more difficult surgical candidates and may have higher mortality rates than nonobese patients.

Prior thoracotomy or pleurodesis was once considered to be a relative contraindication to transplantation due to increased difficulty with the transplant pneumonectomy as well as with an increased risk of bleeding. Extensive prior chest surgery with lung resection remains a relative contraindication to LT. Despite this, transplantation can be successfully performed for these patients and for many of them SLT may be the best option. Other relative contraindications include well-controlled human immunodeficiency (HIV) disease, and hepatitis B or C without active cirrhosis.

**Absolute Contraindications**

The 2014 international guidelines identified several absolute contraindications to LT including untreated major organ dysfunction,
uncorrectable atherosclerotic disease, acute medical instability, and uncorrectable bleeding diatheses [3]. Active malignancy within the prior 2 years is also a contraindication to transplantation. For patients with a history of breast cancer greater than stage 2, colon cancer greater than Duke A stage, renal carcinoma, or melanoma greater than or equal to level 2, the waiting period should be at least 5 years. Restaging is suggested before transplant listing.

Severe non-osteoporotic skeletal disease, such as kyphoscoliosis, is often an absolute contraindication to transplantation, primarily because of the technical difficulties encountered during surgery, and residual restrictive lung disease after transplantation.

Drug abuse and alcoholism are considered to be contraindications to transplantation because patients with these conditions are associated with a high risk for noncompliance. Patients who continue to smoke despite having end-stage pulmonary disease are not candidates for LT. Transplant centers require patients to abstain from cigarette smoking, alcohol use, or narcotics use for 6 months to 2 years before being considered for lung transplant evaluation.

The patient must be well motivated and emotionally stable to withstand the extreme stress of the pretransplantation and perioperative periods. A history of nonadherence, significant psychiatric illness, or lack of an adequate support system are absolute contraindications. In addition, lack of potential for rehabilitation or extreme obesity ≥35.0 kg per m², are also absolute contraindications to LT. Chronic infection with pan-resistant organisms or active *Mycobacterium tuberculosis* infection also preclude LT.
Until the spring of 2005, as established by the United Network of Organ Sharing, lungs were allocated primarily by time on the waiting list and not by necessity. In the spring of 2005, the system for donor allocation for lungs was revised and priority was assigned for lung offers on the basis of a benefit or need-based Lung Allocation Score (LAS) [10,11]. The LAS is calculated using the following measures: (1) waitlist urgency measure (i.e., the expected number of days lived without a transplant during an additional year on the waitlist); (2) posttransplant survival measure (i.e., the expected number of days lived during the 1st year after transplant); and (3) the transplant benefit measure (i.e., the posttransplant survival measure minus waitlist urgency measure) [12]. Now 10 years later, many of the goals of the system (decreased waiting list deaths and times, and prioritizing patients by urgency rather than time on the list) are being accomplished, with comparable survival rates except for those with the very high LAS scores (>46 in one study and >60 in another) [13–15]. In a large single-center study, patients with high LAS scores of ≥50 had lower survival rates at 30 days, 90 days, 1 year, and 3 years (92.6%, 87.8%, 71.5%, 52% vs. 96.9%, 93.5%, 83.2%, and 73.9%, respectively) and increased morbidity compared with those with LAS < 50 including prolonged need for ventilator support, need for tracheotomy, and longer ICU stays [16]. There also appears to be a stepwise decline in posttransplantation survival as the LAS score increases. In another study, patients with high LAS scores had higher morbidity including requirements for dialysis, infections, and longer lengths of stay [17]. Since the implementation of the LAS, the distribution of patient diagnoses on the list, and those transplanted, has also shifted from a majority of COPD patients to an increasing number of patients with pulmonary fibrosis. In addition, sicker patients are being transplanted.

In the United States, donor lungs are first distributed locally, then regionally, and finally nationally. Currently, the median time to transplant for waitlist patients is approximately 4.3 months (range 0.2 to 52 months) [18] and therefore close management of the listed transplant patient is required. Despite this close attention, a small percentage of patients die while awaiting transplantation.

A shortage of donor organs remains the primary factor limiting the number of LTs performed. Contributing to this shortage is the estimate that lungs for transplantation are procured from only 21% of multiorgan donors [19]. The vast majority of transplanted lungs are from brain-dead donors. A small number of LT procedures involving living related donors
and an increasing number of lung donors from donation after circulatory death (DCD), previously referred as non–heart-beating donors, have been performed at institutions specializing in these procedures [20,21]. In a recent meta-analysis of DCD donation in LT involving 271 DCD and 2,369 donation after brain death (DBD) donors, no differences were found in 1-year survival, incidence of PGD, or acute rejection [20]. In the DCD Registry of the ISHLT, 306 DBD transplantations were compared to 3,992 DCD transplantations. The study found that 30-day, 1-year, and 3-year survival rates were comparable between the two groups. The DCD recipients had a slightly longer hospital stay following transplantation 18 days versus 16 days ($p = 0.016$) [21]. Ethical issues regarding DCD donation were recently reviewed in a multisociety policy statement [22].

The usual donor selection criteria are age younger than 60 to 65 years, no history of clinically significant lung disease, normal results from a sputum Gram stain, and a limited history of smoking (less than 20 pack-years). In addition, the lung fields should be clear as demonstrated by chest radiograph, and gas exchange should be adequate as demonstrated by a partial pressure of arterial oxygen ($\text{PaO}_2$) > 300 mm Hg, while receiving fractional inspired oxygen ($\text{FiO}_2$) equal to 1, or a $\text{PaO}_2/\text{FiO}_2$ ratio of more than 300, with a positive end-expiratory pressure (PEEP) of 5 cm H$_2$O. Bronchoscopy is also part of the evaluation of the donor. The main goal of the endobronchial evaluation is to rule out gross aspiration or purulent secretions in the distal airways. Lungs from extended donors (i.e., those who do not meet all of the criteria listed earlier) are now more frequently being transplanted in an attempt to expand the donor pool. Commonly extended criteria include the use of lungs from older donors and those from smokers [23,24]. In the Euro transplant community, lungs from extended donors are used for rescue offers with comparable outcomes [25]. Some centers are actively engaged in developing protocols for optimizing marginal donor lungs, thereby rendering them transplantable [26–29]. By instituting a protocol including educational and donor management interventions, and changing donor classification and selection criteria, a single-organ procurement organization was able to increase the percentage of lungs procured from 11.5% to 22.5% with an increase in the number of procedures performed, without adverse recipient outcomes [29]. A similar study using a protocol of protective ventilation including ventilator recruitment maneuvers, high levels of PEEP, fluid restriction, and hormonal resuscitation therapy also showed increased procurement rates from 20% to 50% without compromised survival or incidence of PGD [26]. The use of lung protective ventilation strategies such as low tidal volume ventilation to limit lung injury is now recommended when managing the potential lung donor, resulting in adequate functioning lungs [26–28,30]. A multicenter randomized controlled trial of potential organ donors managed with conventional
versus protective ventilator strategies revealed that the latter resulted in a significant increase in the number of eligible (54% vs. 95%) and harvested (27% vs. 54%) lungs for LT. There were no differences in 6-month survival among recipients receiving lungs from donors ventilated by either strategy [28].

A new development in lung donation has been the use of ex vivo lung perfusion (EVLP), which in essence “reconditions” lungs that have previously not been acceptable for transplantation. In a prospective nonrandomized clinical trial from Toronto examining high-risk donor lungs transplanted after 4 hours of EVLP, the investigators found results similar to those obtained with conventionally selected lungs, including incidence of PGD, 30-day mortality and 1-year mortality, bronchial complications, duration of mechanical ventilation, and hospital and ICU length of stay [31,32]. Other studies using EVLP found similar results in addition to similar incidences of acute rejection and infection [33,34].

Donors are excluded from potential lung donation if there is evidence of active infection, human immunodeficiency virus, hepatitis, or malignancy. Donor and recipient compatibility is assessed by matching A, B, and O blood types and chest wall size. Human leukocyte antigen (HLA) matching is not routinely performed in LT except in patients with history of preformed donor-specific antibodies.
SURGICAL TECHNIQUES

Initially, double-lung transplantation was the procedure of choice with the anastomosis placed at the level of the trachea. However, the rate of ischemic airway complications was prohibitive. Now, SLT or BLT (essentially sequential SLT) with anastomoses at the level of the main stem bronchi is the preferred surgical technique. At the time of donor harvest, the donor lung is usually removed through a median sternotomy. The pulmonary veins are detached from the heart with a residual 5-mm cuff of left atrium. Each pulmonary artery and the main stem bronchus are transected between two staple lines. During transportation to the recipient site, the partially inflated donor lung graft is placed into preservation solution, usually a low-potassium dextran solution with extracellular electrolyte composition or a modified Euro-Collins solution with an intracellular electrolyte composition at 4°C.

For SLT, the recipient surgery is performed more commonly through a posterolateral thoracotomy or on occasion through a midsternotomy, or vertical axillary muscle-sparing minithoracotomy. Most centers start with the bronchial anastomosis, without a vascular anastomosis of the bronchial circulation of the recipient and donor lungs. Initially, most transplant procedures involved an end-to-end anastomosis, which was wrapped with a piece of omentum or pericardial fat with an intact vascular pedicle for assistance in bronchial revascularization. Subsequently, a telescoping technique was recommended, with the recipient and donor bronchi overlapping by approximately one cartilaginous ring. This procedure allowed the recipient’s intact bronchial circulation to supply the donor bronchus. More recently, most anastomoses are performed with an end-to-end single suture in the membranous portion and a single or continuous suture in the cartilaginous portion, without omental wrap, and telescoping is performed when the donor and recipient bronchi differ in size and there is a natural, unforced telescoping of both bronchi [35].

After the bronchial anastomosis has been performed, the donor pulmonary veins are anastomosed end-to-end to the recipient’s left atrium, and the pulmonary arteries are attached with an end-to-end anastomosis.

BLT is usually performed through a transverse thoracosternotomy (clamshell incision) or less frequently with median sternotomy followed
by sequential single-lung procedures. Cardiopulmonary bypass may be required for patients with pulmonary hypertension or those who cannot tolerate single-lung ventilation or perfusion and who experience marked hypoxemia or hemodynamic instability. Although center specific, an increasing number of cases (nearly 50% of LT procedures at some institutions) are performed with the use of cardiopulmonary bypass.
GENERAL POSTOPERATIVE MANAGEMENT

After LT, patients remain intubated, require mechanical ventilation, and are transferred to the ICU. Most patients are ventilated in a volume-control mode, although in recent years some transplant centers have changed to pressure-control ventilation, or airway pressure release ventilation. In general, low tidal volume ventilation strategies are used. Airway pressures are kept as low as possible so that barotrauma and anastomotic dehiscence can be avoided. Many institutions use routine pharmacologic sedation. Patients are generally maintained with tidal volumes of 6 to 8 mL per kg postoperatively. At most institutions, a low level of PEEP (5.0 to 7.5 cm H₂O) is applied immediately after lung expansion in the operating room and is continued after transplantation. Early extubation is one of the main goals after LT, and lung transplant recipients who do not experience complications are extubated within the first 12 to 24 hours postoperatively if they meet the commonly accepted weaning criteria. Both postural drainage and chest physiotherapy can be routinely employed without concern for mechanical complications at the anastomosis, and patients should perform incentive spirometry soon after extubation.

A recent international survey, with 58% response rate, on mechanical ventilation practices after LT revealed that pressure assist control was used by 37% of respondents and volume assist control by 35%. Tidal volumes were based on recipient, not donor, characteristics, and most respondents selected 6 mL per kg of recipient ideal body weight as a target. Twenty-one percent selected 10 mL per kg, and none selected 15 mL per kg. Most respondents favored limiting FIO₂ over PEEP 69% versus 31% (p = 0.006), and the median minimum PEEP used was 5 cm H₂O and median maximum was 11.5 cm H₂O. In the setting of PGD, the plateau pressure limit for adjusting tidal volume was 30 cm H₂O [36].

Certain patient populations require special ventilator management. Most patients with idiopathic pulmonary hypertension undergo BLT; however, at a few centers some patients undergo SLT for pulmonary hypertension with an increased risk of reperfusion pulmonary edema because nearly all of the perfusion is going to the newly implanted lung. Patients with obstructive lung disease can encounter problems if the delivered tidal volume or the required levels of PEEP are high. Occasionally, clinically significant acute native lung hyperinflation can occur and can compromise the newly transplanted lung and lead to hypotension and hemodynamic instability. To reduce this problem, some transplant centers avoid PEEP for patients undergoing SLT for
obstructive disease. However, the problem is magnified when patients experience reperfusion injury or pneumonia after transplantation; in such cases, the compliance of the transplanted lung is decreased and higher PEEP is required for maintaining oxygenation. As a consequence, the more compliant emphysematous lung becomes overexpanded and can herniate toward the contralateral hemithorax [37]. Attempts to prevent this possible complication by using selective independent ventilation with a double-lumen endotracheal tube have been tried. Lung hyperinflation is associated with a significantly longer stay in the ICU, a longer duration of mechanical ventilation, and a trend toward higher mortality [38].

Pain control is usually provided by opiates, usually fentanyl, administered intravenously, or morphine sulfate via an epidural catheter with a patient-regulated pain-control system.

Because many patients are nutritionally depleted before transplantation as a result of their underlying disease, postoperative nutrition is important. Ideally, enteral nutrition should be provided as soon as tolerated.

Antibiotics are routinely administered for the first 48 to 72 hours after transplantation. Antibiotic regimens include broad-spectrum antibiotic coverage for both gram-negative and gram-positive bacteria. Most centers advocate empiric anaerobic coverage. Gram stains and cultures of sputum from the donor and the recipient may be used when available to guide the choice of appropriate antibiotics. Many centers routinely use antifungal agents such as inhaled amphotericin B, voriconazole, or itraconazole postoperatively. Most transplantation programs administer valganciclovir for CMV prophylaxis if either the patient or the donor IgG serology is CMV-positive before surgery.

Immunosuppression is begun preoperatively with tacrolimus or cyclosporine and corticosteroids. Corticosteroids are administered in the operating room as intravenous methylprednisolone 0.5 to 1 g (usually administered at the time of reperfusion) and then at doses of 1 to 3 mg per kg daily for the next 3 days, followed by 0.8 mg per kg daily and then conversion to an equivalent oral dose. Many centers currently use interleukin (IL)-2 receptor blockers (e.g., basiliximab) for induction immunosuppression. A retrospective registry analysis of the impact of induction therapy on survival following LT showed a survival advantage with the use of interleukin-2-receptor antagonists in both SLT and BLT recipients and in BLT recipients treated with anti-thymocyte globulin (ATG) [39]. After the transplantation procedure, most patients begin a triple immunosuppression protocol with a combination of prednisone, a calcineurin agent, tacrolimus or cyclosporine, and a cell-cycle–inhibiting agent, mycophenolate mofetil or azathioprine [40].
Perhaps the most serious problem in the postoperative period after LT is PGD [41]. A 2005 consensus conference attempted to standardize the grading of PGD on the basis of gas exchange and the presence of radiographic infiltrates (Table 59.2) [42]. When the acute lung injury definition of acute respiratory distress syndrome (ARDS)—a PaO\(_2\)/FiO\(_2\) ratio of less than 200—is used to define the most severe form of PGD (grade 3), it is estimated that as many as 5% to 25% of transplant recipients can develop PGD (grade 3) [42, 43]. PGD is a diagnosis of exclusion; the condition usually occurs hours to 3 days after LT, whereas rejection and infection are more common after the first 24 hours. A stenosis at the venous anastomosis presents with similar signs and symptoms, but this diagnosis can be excluded by transesophageal echocardiography. However, because the timing of these disorders may vary, differentiation may be difficult.

PGD can persist to various degrees for hours to days after LT. Clinically, PGD is characterized by the appearance of new alveolar or
interstitial infiltrates on radiographs, a decrease in pulmonary compliance, an increase in pulmonary vascular resistance, and a disruption in gas exchange. The radiographic findings of these patients include a perihilar haze, patchy alveolar consolidations, and, in the most severe form, dense perihilar and basilar alveolar consolidations with air bronchograms (Fig. 59.1). Pathology reports from biopsy specimens, autopsies, or lung explants removed during retransplantation indicate diffuse alveolar damage. PGD usually stabilizes over the next 2 to 4 days and then begins to resolve, although PGD is the single most common cause of mortality in the first 30 days following transplantation.

PGD is managed supportively with diuretics and mechanical ventilation, often with protective ventilatory strategies [41]. Because endogenous nitric oxide (NO) activity decreases after LT, there are several reports of the use of inhaled NO for hypoxemia and for pulmonary hypertension as a consequence of graft dysfunction after transplantation [44,45]. However, in one randomized, placebo-controlled trial (84 patients), the prophylactic inhalation of NO 10 minutes after reperfusion and for a minimum of 6 hours, was not shown to be
beneficial for hemodynamic variables, reperfusion injury, oxygenation, time to extubation, length of intensive care or hospital stay, or 30-day mortality [46]. The use of artificial surfactant replacement has also been examined [47,48]. An open randomized prospective trial studying the use of instilled bovine surfactant immediately after establishment of the bronchial anastomosis, showed improved oxygenation and decreased PGD, shortened intubation time, and enhanced early post-LT recovery in the treatment group, although an unusually high incidence of PGD was found in the control group [47]. ECMO is also used for severe PGD unresponsive to protective lung ventilation with a hospital survival rate of 42% in an analysis of the Extracorporeal Life Support Organization registry study [49]. When used in this setting, ECMO should be initiated early to minimize the complications associated with prolonged mechanical ventilation. Veno-venous ECMO is the most commonly used ECMO for PGD, particularly since PGD usually resolves in a relatively short period of time. Retransplantation has also been performed, but the outcomes for patients undergoing retransplantation for PGD has been very poor.

Severe PGD usually leads to compromised short-term outcomes, including increase in the duration of mechanical ventilation and lengths of stay, poor 1-year survival rates, and compromised function among survivors. Long-term outcomes, such as pulmonary function and the incidence of bronchiolitis obliterans, are also impacted, and more severe PGD and longer duration of PGD are associated with the development of bronchiolitis obliterans syndrome (BOS) [50–52].

Although the mechanisms of PGD have not been completely delineated, several contributing factors have been postulated, including the disruption of lymphatics, bronchial vasculature, or nerves, and lung injury occurring either during preservation of the graft or after reperfusion [53]. Most likely, PGD is due to ischemia-reperfusion injury leading to increased capillary permeability and noncardiogenic pulmonary edema.

Multiple risk factors may be associated with the development of PGD [41,43,54–56]. Risk factors for severe PGD include some donor characteristics such as smoking history and hemodynamic instability following brain death; some events during the surgical procedure such as increased FIO₂ during allograft reperfusion, single-lung transplant, use of cardiopulmonary bypass, prolonged ischemic times, and blood product transfusions; and finally some recipient characteristics such as obesity, a preoperative diagnosis of sarcoidosis, and pre- and postoperative pulmonary arterial hypertension. Antibody-mediated rejection has also recently been postulated to be a risk factor for PGD [57].

ICU Outcomes
Few data are available for predicting outcomes and length of ICU stay after LT. It is known that the duration of mechanical ventilation is prolonged and the ICU mortality increased for patients who experience PGD. One study found that an immediate postoperative PaO₂/FIO₂ ratio of less than 200 predicted an ICU stay of 5 days or more [58]. Another study examined the value of intravascular volume status and central venous pressure (CVP) for predicting ICU outcomes; the results indicated that a CVP higher than 7 mm Hg after transplantation was associated with a longer duration of mechanical ventilation, longer ICU and hospital stays, and higher 2-month mortality rates [59].

Among patients requiring prolonged ICU stays, those who underwent tracheostomy were more likely to have undergone BLT, required cardiopulmonary bypass during the procedure, experienced postoperative pneumonia, had more significant PGD at 48 hours, had longer initial periods of mechanical ventilation, and required reintubation more often [60].

Late Complications Requiring Admission to the ICU

The number of lung transplant recipients who are admitted to the ICU is expected to increase as the number of long-term survivors increases. The postoperative mortality rate has decreased because of improved surgical techniques and perioperative care, and approximately 97% of patients are discharged alive after transplantation [2]. However, after this immediate posttransplantation period, lung transplant recipients are more likely than some other solid-organ transplant recipients to experience infection or rejection that often require readmission to the ICU.

Nearly 25% of lung transplant recipients require an ICU admission after the initial hospital discharge. The most common admission diagnoses are respiratory failure and sepsis. These patients frequently require mechanical ventilation (53%), and the mortality rate is generally close to 40%. Prognostic factors for mortality include higher acute physiology and chronic health evaluation (APACHE) scores, a forced expiratory volume in one second (FEV₁) lower than the patient’s best posttransplantation FEV₁, nonpulmonary organ dysfunction, low-serum albumin level, and longer duration of mechanical ventilation [61]. Patients admitted with a diagnosis of BOS who require mechanical ventilation are at the highest risk of mortality. In a large single-center study examining all admissions to the MICU in patients >30 days following LT, reasons for admission included respiratory failure in 50.5%
and acute rejection in 16%. One quarter of patients required hemodialysis, and 53.5% required mechanical ventilation. In the study cohort, hospital survival was 88/101, but 6-month survival was 56.4%. Predictors of hospital survival were APACHE score on admission and SLT. Functional status at discharge was an independent predictor of 6-month survival [62]. In another study, again examining ICU admissions at >30 days post-LT in patients with diagnoses of idiopathic pulmonary fibrosis and COPD, 93% of patients required mechanical ventilation. Septic shock was the reason for admission in 55% of patients. ICU mortality was 62.5%. Mortality was associated with more frequent hospital admissions, a high severity score (SOFA), a diagnosis of sepsis, and requirement for mechanical ventilation. There was a higher incidence of BOS in nonsurvivors [63].

The long-term survival of patients who recover from the ICU stay is also compromised; however, a high percentage of patients (50%) can still enjoy long-term survival after an ICU admission.

A recent study supports the use of high-flow nasal cannula (HFNC) as supportive therapy for patients readmitted to the ICU for acute respiratory failure and was associated with a decreased risk of mechanical ventilation (absolute risk reduction of 29.8%). The number needed to treat to prevent one intubation was three [64]. In addition, those supported with HFNC had increased survival rates and did not experience adverse events.

Airway Complications

Because of the lack of revascularization of the bronchial circulation, anastomotic complications, such as bronchial dehiscence, bronchial stenosis, and bronchial infection, are the main airway complications reported in the first few weeks to months after LT [65,66]. The incidence of anastomotic complications has decreased as surgical techniques have improved and surgeons have gained experience with the procedure. The reported incidence of this complication ranges widely: some studies report it to be as high as 33%; others, as low as 1.6%. However, in reality, most recent series suggest a range of 7% to 18% [67], with a related mortality rate of 2% to 4%. Risk factors for airway complications include ischemia of the donor bronchus during the posttransplantation period, due to loss of bronchial blood flow (only the pulmonary vessels are revascularized during LT surgery), surgical techniques for the anastomosis, length of the donor bronchi, acute rejection, and bronchial infections.

Airway complications can be classified as early or late. Early airway complications usually occur during the first 4 to 12 weeks after transplantation and manifest themselves as a partial or complete
anastomotic dehiscence or a fungal (usually *Aspergillus* or *Candida* species) or bacterial (usually *Staphylococcus* or *Pseudomonas* species) anastomotic infection. These conditions can subsequently result in anastomotic strictures or bronchomalacia. Clinically, bronchial dehiscence may cause prolonged air leaks in the early posttransplantation period. In some cases, the dehiscence may also lead to infection or the formation of peribronchial abscesses or fistulas. The results of chest radiographs and computed tomography (CT) scans are usually nonspecific; however, the appearance of extraluminal air on chest CT scans is very sensitive and specific for the diagnosis of anastomotic dehiscence.

Bronchoscopy is the preferred diagnostic method for evaluating the bronchial anastomosis. The initial bronchoscopies are done usually before extubation and again before discharge. In addition, the anastomosis is also evaluated carefully during surveillance or clinically indicated bronchoscopy particularly during the 1st year. The integrity of the mucosa should be assessed, and specimens from a bronchial wash or brush should be sent for cultures and cytologic examination. If there is any evidence of infection, antibiotics and antifungals (usually inhaled amphotericin with or without itraconazole or voriconazole) should be administered on the basis of culture results.

Late bronchial anastomotic complications, including stenosis (most common), bronchomalacia, and development of exophytic granulation tissue are often the result of ischemia, infection, or dehiscence during the early weeks after transplantation. These complications manifest themselves as cough, shortness of breath, wheezing, dyspnea on exertion, and worsening obstruction as documented by pulmonary function testing. The characteristic flow volume loop demonstrates a concave appearance in both the inspiratory loop and the expiratory loop. Bronchial strictures or stenosis may also be seen on chest radiographs or CT scans, or by bronchoscopy. Therapeutic options for anastomotic complications include balloon dilation of a stricture, stent placement, cryotherapy, argon beam coagulation, laser procedures, and, rarely, surgery.

**Rejection**

Graft rejection is categorized clinically according to the time of onset after transplantation and the histopathologic pattern. The three types of rejection are antibody-mediated rejection (AMR) which can rarely appear as a form of hyperacute rejection, acute cellular rejection, and chronic rejection. Hyperacute rejection is an acute form of AMR caused by preexisting alloantibodies that bind to the donor vascular epithelium and lead to vessel thrombosis because of complement activation. This was
thought to be a rare complication after LT. However, AMR or humoral rejection is currently an area of active research in the field of LT [68,69]. AMR is characterized by local complement activation or the presence of antibody to donor HLAs and may be a risk factor for BOS [70]. Treatment of AMR includes plasmapheresis, intravenous immunoglobulin and/or rituximab, a monoclonal antibody against the CD-20 antigen.

Acute Rejection

As many as 50% to 55% of patients experience acute rejection during the first postoperative month, and as many as 90% will experience at least one episode of acute rejection within the 1st year [69]. Acute rejection usually occurs between 10 and 90 days after LT. It is not uncommon (20% of lung transplant recipients) for a single patient to experience either recurrent (more than two episodes) and/or persistent (failure to resolve with standard therapy) rejection. Acute rejection usually does not occur as frequently after the first postoperative year. Risk factors for acute rejection are poorly defined, but HLA mismatches may be correlated with its occurrence [71,72].

Clinically, acute rejection manifests itself as cough, shortness of breath, malaise, and fever. Occasionally, the presentation is asymptomatic. The majority of transplantation centers advocate surveillance bronchoscopy for the detection of this condition, although outcome data are not available [40]. Physical examination may detect rales or wheezing. The usefulness of chest radiography depends on the time since transplantation. Typically, during the 1st month the results of chest radiography can be abnormal in as many as 75% of rejection episodes; however, the results of radiography are abnormal in only 25% of rejection episodes that occur more than 1 month after transplantation. The most common radiographic patterns associated with acute rejection are a perihilar flare, and alveolar or interstitial localized or diffuse infiltrates with or without associated pleural effusion. In addition, CT may show ground-glass opacities, septal thickening, and volume loss. New pleural fluid or increases in the amount of pleural fluid produced during the 2nd to 6th week after LT is common among patients with acute lung rejection. The characteristics of the fluid are consistent with those of an exudate: the total lymphocyte count is often more than 80% of the total number of white blood cells.

Physiologic findings during periods of acute rejection include hypoxemia and deterioration in pulmonary function. Pulmonary function abnormalities are characterized by at least a 10% to 15% decline in $\text{FEV}_1$.
from baseline and/or at least a 20% decline in forced expiratory flow (FEF) over 25% to 75% of expired vital capacity. Once again, these changes are nonspecific and can also be seen with infectious processes and graft complications.

Because clinical criteria alone cannot differentiate acute rejection from infection and less common graft complications, transbronchial biopsy (TBBx) with bronchoalveolar lavage (BAL) has become the primary diagnostic procedure. The sensitivity of diagnosing acute rejection by TBBx ranges from 61% to 94%, and the specificity ranges from 90% to 100%. A histologic grading system for acute pulmonary rejection was proposed in 1990 and revised in 1996 and 2007 [73]. Pathologically, acute rejection is characterized by perivascular, mononuclear lymphocytic infiltrates with or without airway inflammation; histologically, it is graded from A₀ to A₄ on the basis of the degree of perivascular inflammation. In addition, the airway can be involved by lymphocytic bronchitis or bronchiolitis, which is graded from B₀ to Bₓ. As rejection progresses, the perivascular lymphocytic infiltrates surrounding the venules and arterioles become dense and extend into the perivascular and peribronchiolar alveolar septa. Severe rejection may involve the alveolar space; parenchymal necrosis, hyaline membranes, and necrotizing vasculitis have been described; and respiratory failure requiring mechanical ventilation can occur.

Once acute rejection has been diagnosed, treatment consists of augmenting the level of immunosuppression. Intravenous methylprednisolone (10 to 15 mg per kg daily for 3 days) followed by an increase in the maintenance regimen of prednisone regimen to 0.5 to 1 mg per kg daily, with tapering over the next several weeks, is a standard treatment regimen. Maintenance immunosuppression should also be augmented. Typically, symptoms resolve in days, and histologic follow-up 3 to 4 weeks later should demonstrate resolution. Recurrent or persistent acute rejection may require alteration of the baseline immunosuppressive regimen. Lympholytic therapy, methotrexate, photophoresis, total lymphoid irradiation, and aerosolized cyclosporine have been used with varied success [74].

**Chronic Lung Allograft Dysfunction**

Chronic lung allograft dysfunction (CLAD) encompasses varied presentations of progressive allograft dysfunction with obstructive and restrictive physiology [75]. The most common form of CLAD has been equated with the histologic finding of obliterative bronchiolitis (OB); this form of chronic rejection is a primary cause of morbidity and mortality after LT and the leading single cause of death more than 1 year after transplantation [1]. The incidence of OB ranges from 35% to 50%. OB has
been defined clinically by an obstructive functional defect and histologically by obliteration of terminal bronchioles. OB generally occurs at a mean of 16 to 20 months after LT, but it has been reported as early as 3 months after transplantation. More than 50% of recipients will experience some degree of OB by 5 years after transplantation [1]. A less common form of CLAD, the restrictive allograft syndrome (RAS), contributes to approximately 25% to 35% of the reported cases and carries a worse prognosis than BOS. It is characterized by various stages of diffuse alveolar damage and extensive fibrosis in the alveolar interstitium, visceral pleura, and interlobular septae. RAS presents radiologically as upper lobe–dominant fibrosis and/or interstitial opacities sometimes often with associated pleural thickening and with a restrictive pattern in the lung function tests (Total lung capacity [TLC] below 90% of the best baseline posttransplant) [75,76].

The causes of and risk factors for OB remain unclear. Several possible risk factors have been proposed, including uncontrolled acute rejection, lymphocytic bronchiolitis, CMV pneumonitis, CMV infection without pneumonitis, community-acquired respiratory viruses, gastroesophageal reflux disease, PGD, AMR, HLA-A mismatches, total HLA mismatches, absence of donor antigen-specific hyporeactivity, non-CMV infection, older donor age, and bronchiolitis obliterans with organizing pneumonia [50,51,77–79]. The most consistently identified risk factor is acute rejection, particularly in those patients who experience recurrent, high-grade episodes of acute rejection.

Clinically, OB can manifest itself as an upper respiratory tract infection and can be mistakenly treated as such. Other patients exhibit no clinical symptoms, but pulmonary function testing demonstrates gradual obstructive dysfunction. FEV$_1$ has been the standard spirometric parameter used for diagnosis, but midexpiratory flow rates may be a more sensitive parameter for early detection.

Typically, chest radiographs are not helpful in the diagnosis of OB because their results are unchanged from the results of baseline posttransplantation radiographs. High-resolution CT scans may show peripheral bronchiectasis, patchy consolidation, decreased peripheral vascular markings, air trapping, mosaicism, tree-in-bud changes, and bronchial dilation; these findings may aid in the diagnosis of OB [80]. Air trapping on end-expiratory high-resolution CT scans has been shown to be a sensitive (91%) and accurate (86%) radiologic indicator of OB, but it may not be able to provide an early diagnosis of this disorder. As with acute rejection, TBBx is used to diagnose OB, but primarily to exclude other diagnoses. The classic pathologic finding is constrictive bronchiolitis. Unfortunately, the sensitivity of TBBx for diagnosing OB is low (range: 15% to 87%), and the diagnosis of OB is often made by exclusion. OB is graded physiologically on the basis of the degree of
change in pulmonary function (FEV$_1$) from baseline [78]. Because of the variability in obtaining bronchioles by TBBx, the ISHLT has established a staging system for BOS. This staging is based on a reduction in FEV$_1$ of more than 20% from baseline after transplantation and is associated with a decrease in the FEF 25% to 75%, with or without the pathologic documentation of OB [78].

Once OB has been diagnosed histologically or clinically by excluding alternative diagnoses, treatment involves administering high-dose methylprednisolone followed by a tapering course of oral corticosteroids. Therapy may stabilize pulmonary function, but it only rarely results in substantial improvement. Alternative immunosuppressants such as sirolimus have also been associated with stabilization of pulmonary function when used as rescue treatment for BOS. Lympholytic depleting agents such as ATG are the most commonly used rescue medications if there is no clinical response to corticosteroids. Several studies have shown prevention, stabilization, and/or improvement in BOS when azithromycin is added to the regimen or used prophylactically, likely due to the immunomodulating effects and is now a widespread practice [81,82]. Other alternatives with limited clinical success include alemtuzumab, basiliximab, methotrexate, total lymphoid radiation, and photopheresis.

Infection, including bronchiectasis, frequently complicates intensive immunosuppression for OB and may result in death. Pseudomonas is a common offender, and aerosolized aminoglycoside antibiotics or suppressive quinolone treatment may be considered. Because most cases of OB can only be stabilized, strategies directed at prevention, early diagnosis, and treatments are necessary for the preservation of lung function. Retransplantation has been performed with varied results. Survival rates are somewhat lower than those after the initial transplantation and are superior when performed for the indication of BOS, performed more than 1 year following the initial transplant and when a bilateral transplant is performed (1 year, 71%; 3 years, 46%; and 5 years, 34%) [1,83].

Infectious Complications

Infections are an important cause of early and late morbidity and mortality after transplantation and are the leading single specific cause of death during the 1st year following the transplantation procedure [1,84]. The incidence of infection is significantly higher among recipients of lung...
transplants than among recipients of most other solid-organ transplants; this higher incidence may be related to the continuous exposure of the allograft to the environment. Other predisposing factors include a diminished cough reflex because of denervation, poor lymphatic drainage, decreased mucociliary clearance, recipient-harbored infection, and, occasionally, transfer of infection from the donor organ. Nosocomial infections, such as urinary tract infections, ventilator-assisted pneumonia, and infections at the site of the surgical wound or the vascular access, also occur during the early postoperative period. However, in most circumstances the allograft(s) is/are the primary site of infection.

**Bacterial Infections**

Bacterial pneumonia is the most common life-threatening infection that develops during the early postoperative period. Its incidence during the first two postoperative weeks is reported to be as high as 35% [84–87], and in a single-center retrospective cohort study, 68% of patients developed at least one episode of pneumonia [88]. In another single-center study, 12% of patients suffered a ventilator-associated pneumonia, resulting in increases in hospital length of stay, increase in duration of mechanical ventilation, and an increase in hospital mortality.

Pseudomonas and Enterobacteriaceae were the most common pathogens. Gastroperesis was associated with the development of pneumonia in this study [89]. Common organisms include *Pseudomonas aeruginosa* and *Staphylococcus* species. The incidence of perioperative bacterial pneumonia has been reduced to as low as 10% by prophylaxis with broad-spectrum antibiotics, usually an antipseudomonal cephalosporin and clindamycin, and by routine culture of the trachea of both the donor and the recipient at the time of transplantation. Prophylactic antibiotics are usually discontinued after 3 days if the results of cultures are negative; the antibiotics are tailored to the cultured organisms if the results are positive. For transplant recipients with bronchiectasis, postoperative bacterial prophylaxis is usually continued for 14 days. The incidence of bacterial pneumonia is high during the first 6 months after transplantation but decreases thereafter, although a second late peak of incidence often occurs when immunosuppression is augmented for the treatment of chronic rejection. During the early posttransplantation period, bacterial infection due to *Staphylococcus* or, less commonly, *Pseudomonas* can develop at or distal to the site of the anastomosis. It is often difficult to distinguish pneumonia from other early graft complications, such as reperfusion injury, pulmonary edema, rejection, and other causes of infection. In addition, differentiating between colonization and invasion may be difficult and often requires invasive
procedures such as bronchoscopy with BAL, quantitative sterile brush sampling, or TBBx.

Other Infections

Atypical pneumonias, including those due to Legionella, Mycobacteria, and Nocardia, are uncommon during the first month after transplantation but occur among 2% to 9% of recipients of lung or heart-lung transplants. At transplantation centers that routinely administer prophylaxis with trimethoprim–sulfamethoxazole during the 1st year after transplantation and continue or reinitiate it when immunosuppression is augmented, the incidence of pneumocystis pneumonia is less than 1%.

Most opportunistic infections occur within 6 months after transplantation. Sustained immunosuppression leading to a decrease in cell-mediated immunity predisposes the patient to infection with opportunistic organisms such as Aspergillus, Mycobacterium, Nocardia, and geographically endemic fungi.

Viral Infections

Viral infections are a primary cause of morbidity and mortality among lung transplant recipients. During the first 6 months after transplantation, CMV accounts for most of the viral infections among these patients [84,87,90]. The typical time period for the development of CMV infection is 30 to 150 days postoperatively; the incidence of illness (i.e., infection and disease) is approximately 50%. Risk factors for CMV disease depend on the serology of the donor and the recipient and on the use of high-intensity immunosuppressive therapy, including cytolytic therapy. Approximately 15% to 35% of CMV-positive patients who receive grafts from either CMV-positive or CMV-negative donors experience CMV disease, whereas approximately 55% of CMV-negative patients who receive a graft from a CMV-positive donor may experience CMV disease. Most studies indicate that CMV pneumonitis contributes to the development of chronic rejection [78].

CMV can cause a wide spectrum of disease, ranging from asymptomatic infection, such as shedding of the virus in the urine or BAL, to widespread dissemination. The most common presentation of CMV among lung transplant recipients is pneumonitis, but the infection may also present as gastroenteritis, hepatitis, or colitis. CMV pneumonitis can often be confused with acute rejection. Clinical findings of CMV pneumonitis include fever, cough, flu-like illness, hypoxemia, an interstitial or alveolar infiltrate, and leukopenia. A definitive diagnosis of invasive disease requires cytologic or histologic changes in a cell.
preparation or in tissue. Therefore, diagnosis often requires flexible bronchoscopy with TBBx and BAL; this combination can detect 60% to 90% of CMV pneumonias. Currently, plasma-based polymerase chain reaction (PCR) assays are used to screen patients and to detect CMV infection [91]. The risk of CMV pneumonitis after LT is usually related to the serum concentration of CMV DNA, and this measure is used in many programs for the preemptive management of CMV.

The pathologic hallmark of CMV infection is a cytomegalic 250-nm cell containing a large central basophilic intranuclear inclusion. This inclusion is referred to as an “owl’s eye” because it is separated from the nuclear membrane by a halo. Identifying CMV cytologically is very specific (98%) but lacks sensitivity (21%) for detecting the presence of infection. Other pathologic findings in the lung parenchyma of patients with CMV pneumonia include a lymphocytic and mononuclear-cell interstitial pneumonitis.

Ganciclovir intravenous and oral valganciclovir are currently the mainstays of therapy for invasive CMV disease [90]. Bone marrow toxicity is one of the primary limiting side effects of ganciclovir therapy and may necessitate conversion to an alternative agent such as foscarnet. Most centers also use CMV-specific hyperimmunoglobulin to treat CMV disease.

Prophylaxis against CMV infections has become an important strategy at most transplantation centers. Initially, some centers attempted to match CMV-negative recipients with CMV-negative donors; however, the limited donor supply did not allow the continuation of this practice. The use of CMV-negative blood products is advocated. Prophylaxis with ganciclovir or valganciclovir seems to be effective in delaying the onset of CMV infection. Most centers give prophylaxis to all patients except CMV-negative recipients who receive grafts from CMV-negative donors. Prophylaxis is usually recommended for at least 90 days, but the majority of centers, particularly for CMV-negative recipients of grafts from CMV-positive donors, will continue prophylaxis for at least 1 year. A randomized, controlled, multicenter study examined the efficacy of extending valganciclovir prophylaxis from the standard 3 months to 12 months in at-risk (either donor or recipient CMV-positive) patients. The investigators found a significant reduction in CMV infection, disease, and disease severity without increased ganciclovir resistance or toxicity among those patients receiving the longer course of therapy [92]. For patients at highest risk of infection, CMV hyperimmunoglobulin may be added to the regimen. Preemptive strategies, such as initiating treatment
when a high level of CMV DNA is detected by PCR, may also delay and decrease the severity of CMV infection and has become the standard of care at many centers. Other viruses that affect lung transplant recipients include herpes simplex virus (early after transplantation), community-acquired respiratory viruses, such as respiratory syncytial virus, other paramyxoviruses (such as parainfluenza), influenza virus, metapneumovirus, and adenovirus [93]. Some transplantation programs initiate prophylaxis with acyclovir for herpes infection after the discontinuation of ganciclovir. Ribavirin has been used to treat respiratory syncytial virus infection in both nebulized and oral form, although the former is associated with bronchospasm and potential teratogenicity to health care workers.

Fungal Infections

Fungal infections are more common among recipients of LTs than among recipients of some other solid-organ transplantations [94,95]. The overall incidence of invasive fungal infection after LT ranges from 15% to 35%. Such infections usually develop during the first few months after transplantation. Fungal infections carry the highest morbidity and mortality rates of all infections after transplantation; mortality rates can range from 40% to 70%.

Aspergillus species such as A. fumigatus, A. flavus, A. terreus, and A. niger can be colonizing organisms; can cause an infection that suggests an indolent, progressive pneumonia; or can cause an acute fulminant infection that disseminates rapidly. Aspergillus can invade blood vessels and may appear as an infarct on chest imaging or present with hemoptysis. The radiographic findings of pulmonary aspergillosis include focal lower-lobe infiltrates, patchy bronchopneumonic infiltrates, single or multiple nodules with or without cavitation, thin-wall cavities, and opacification of the entire lung graft. High-resolution CT scans may reveal a halo sign that is believed to be pathognomonic for angioinvasive fungal infections such as aspergillosis. Other manifestations of Aspergillus infection include pseudomembranous tracheobronchitis, often at and distal to the site of the anastomosis. Diagnosing invasive aspergillosis requires identifying organisms within tissues. These organisms can appear as septate hyphae that branch at acute angles and can be detected on hematoxylin-eosin and methenamine silver stains. Survival rates for patients with Aspergillus infection have been improved by the early initiation of broad-spectrum azoles (such as voriconazole or itraconazole, and more recently posaconazole), sometimes with the addition of an echinocandin, and a reduction in immunosuppressive therapy [96]. In patients with airway involvement
with *Aspergillus* and for short-term prophylaxis following transplantation, inhaled amphotericin may be used. It is now rare to require systemic amphotericin or the less nephrotoxic liposomal formulation of amphotericin B. Prophylaxis with the azoles (voriconazole or itraconazole) for 3 to 6 months, and/or with aerosolized amphotericin, has shown promise for decreasing the incidence of *Aspergillus* infection after transplantation.

Candidal infections may occur during the early postoperative period but usually do not cause invasive disease. *Candida* species can cause a variety of syndromes among LT recipients; these syndromes include mucocutaneous disease, line sepsis, wound infection, and, rarely, pulmonary involvement. Fluconazole and caspofungin have emerged as effective alternatives for treating infections caused by *Candida albicans*. Fluconazole appears to be less active against other *Candida* species such as *C. glabrata* and *C. krusei*.

Less common causes of fungal infections among lung transplant recipients include *Cryptococcus neoformans* and the dimorphic fungi (*Coccidioides*, *Histoplasma*, and *Blastomyces*). The broad-spectrum azole agents are the initial therapeutic choices for treating serious infections with the invasive mycoses. Amphotericin B can be used for disseminated disease. The dose, duration of therapy, and alternative therapies differ depending on the organism.

### Immunosuppression

After LT, a typical regimen for the maintenance of immunosuppression consists of tacrolimus at a dose of approximately 0.1 mg per kg orally every day in two divided doses (adjusted to maintain a serum concentration of 8 to 15 ng per mL), or cyclosporine 5 mg per kg orally every day in two divided doses (with dose adjusted to maintain serum concentrations of 250 to 350 ng per mL), and mycophenolate mofetil at a dose of 1 to 3 g daily, or azathioprine 1 to 2 mg per kg daily (adjusted to maintain a leukocyte count higher than 4,000 to 4,500 per mL), and prednisone approximately 0.5 mg per kg daily for the 1st month and then tapered by 5 mg per week over the next few months to a final maintenance dose of 5 mg per day. A minority of transplantation programs completely discontinue the administration of prednisone approximately 1 year after transplantation. The role of sirolimus after LT remains to be established. It is recommended that sirolimus not be used in the early perioperative period (<10 to 12 weeks) due to impaired wound healing.

Physicians caring for transplant recipients must be aware of the numerous drugs that can interact with tacrolimus and cyclosporine. For example, the azoles cause a significant increase in the serum
concentrations of tacrolimus and cyclosporine. Likewise, discontinuing azole agents without increasing the dose of tacrolimus or cyclosporine can cause an acute and life-threatening decrease in the therapeutic concentrations of these drugs. Interactions with macrolide antibiotics, calcium-channel blockers, and gastric motility drugs have also been reported. The concentrations of tacrolimus or cyclosporine are decreased by rifampin and anticonvulsants.

All immunosuppressants are associated with toxicity and drug interactions [97,98]. The details of these complications are discussed in chapter 63. A unique toxicity of the calcineurin agents particularly when used with sirolimus include thrombotic microangiopathy [99].

Miscellaneous Complications

Another possible complication of LT is postoperative hemorrhage, requiring reexploration. One of the early clues to this diagnosis is radiographic evidence of a hemothorax or what appears to be a retained clot, or a large volume of blood draining from the thoracostomy tubes. This complication may occur more frequently among patients who require cardiopulmonary bypass with its attendant requirement for anticoagulation or among patients with pleural adhesions from previous procedures such as pleurodesis or diagnostic or therapeutic lung surgery. Persistent air leaks can occasionally occur but are unlikely unless the bronchial anastomosis loses its integrity because the lung parenchyma is normally not entered during a routine LT procedure.

In addition to the bronchial anastomotic complications discussed earlier, vascular anastomotic complications can occur. A stenosis at the venous anastomosis is indicated by radiographic evidence of pulmonary edema and infiltrates; this condition can be confused with PGD and is usually diagnosed by transesophageal echocardiography. A stenosis at the arterial anastomosis is suggested by unexplained gas exchange abnormalities and pulmonary hypertension [100]. Phrenic nerve dysfunction and diaphragmatic paralysis, which occur in conjunction with other types of cardiothoracic surgery, occur after LT with an incidence of 3% to 9.3% and are associated with a prolongation in the number of days for which mechanical ventilation is required, an increase in the length of stay in the ICU, an increase in the use of ICU resources, and an increase in the need for tracheostomy [101]. An inability to wean the patient from mechanical ventilation may indicate phrenic nerve dysfunction; the diagnosis can be confirmed by phrenic nerve conduction
studies. For patients who do not require ventilation, the diagnosis of phrenic nerve dysfunction can be made with a fluoroscopic “sniff test,” and more recently with the use of bedside ultrasound. If the injury is the result of stretching of the phrenic nerve or trauma to the nerve during the surgical procedure but the nerve is not completely transected, a slow recovery can be anticipated. Complete transection is rare, but the damage is permanent. Diaphragmatic plication or pacing can be performed in some cases.

Pleural effusions can develop and/or persist following LT. The characteristics of these effusions are usually lymphocyte-predominant exudates and can be associated early on with severing of the lymphatics (i.e., chylous effusion) or with rejection. A single-center study of a large number of lung transplant patients found that 27% of pleural effusions in these patients required drainage. Of the effusions, 96% was exudates, and 27% of patient had infected pleural effusions with organisms such as fungal pathogens (specifically Candida most commonly), followed by bacterial etiologies. These infected effusions were characterized by high lactate dehydrogenase levels and neutrophilia [102]. Other causes of pleural effusions include heart failure, pulmonary embolism, and trapped lung. Rarely pleurodesis or decortication may be required.

Lung transplant recipients also experience gastroparesis, severe gastroesophageal reflux resulting in aspiration pneumonia, and an increased incidence of gastrointestinal emergencies. These conditions include colonic perforation, small-bowel obstruction, diverticulitis, CMV colitis, megacolon, prolonged ileus, ischemic bowel, and pancreatitis [103]. Gastroesophageal reflux may be more severe among transplant recipients with cystic fibrosis.

Renal insufficiency is also a frequent complication among lung transplant recipients. This complication results from a combination of infections leading to sepsis and acute tubular necrosis, or from medication-related renal toxicity. Another study reported an incidence of acute renal failure postoperatively in 39% of patients and identified the use of aprotinin and bilateral lung procedures as risk factors. Acute renal failure was not predictive of late renal dysfunction or decreased long-term survival [104].

Cardiac arrhythmias, especially atrial arrhythmias such as atrial fibrillation, commonly develop in the perioperative period with an incidence of 25% in one study with resulting increase in length of hospital stay and increased 1-year mortality. Risk factors for their development included older age, diagnosis of pulmonary fibrosis, right ventricular dysfunction, right ventricle enlargement and elevated right atrial pressure, left atrial enlargement diastolic dysfunction, and history of coronary artery disease [105]. Another study found an incidence of atrial fibrillation of 35%, which was associated with older age and
cardiopulmonary bypass, with resulting increase in hospital length of stay but no increase in mortality, ICU length of stay, or days on mechanical ventilation [106].

In one series of lung transplant recipients, the incidence of deep venous thrombosis and pulmonary embolism was reported to be 8.6%. This complication was believed to be related to alterations in coagulability leading to a hypercoagulable state or hypercoagulability due to their underlying disease [107,108].

Posttransplant lymphoproliferative disease (PTLD) and other malignancies can occur among lung transplant recipients. The incidence of PTLD after LT reportedly ranges from 1.8% to 9.4% [109,110]. PTLD comprises a heterogeneous group of lymphoid proliferations, usually of the B-cell form, that are strongly associated with the Epstein–Barr virus (EBV). Patients for whom the results of pretransplantation serologic studies are negative for EBV but who receive an organ from an EBV-positive donor and experience seroconversion are at a higher risk of PTLD. Clinically, PTLD usually occurs during the first year after transplantation; it involves the allograft and manifests itself as radiographic findings of solitary or multiple pulmonary nodules. Treatment includes reducing the level of immunosuppression, institution of antiviral therapy, and administering the anti-CD20 monoclonal antibody rituximab. In some cases, chemotherapy or surgery may be indicated.

Significant advances have been made in the field of LT since its inception more than 30 years ago, allowing this procedure to be a successful therapeutic option for patients with end-stage parenchymal or vascular lung disease. However, despite these improvements, numerous complications, many of which are managed by critical care professionals, can arise in this group of patients, and the unique aspects of their care are important.

Specific Critical Care Problems in Heart and Heart–Lung Transplant Recipients
ANDREW W. SHAFFER • KAROL MUDY • SARA J. SHUMWAY

The advent of thoracic organ transplantation has brought new hope to patients who were previously afflicted by end-stage cardiac, pulmonary, or combined cardiopulmonary disease. The first heart transplant was performed on December 3, 1967. Fourteen years passed before the first successful heart–lung transplant was performed on March 9, 1981. Heart–lung transplantation established the potential for lung transplantation as a viable therapeutic option, and the first successful single-lung transplant was performed in 1983 [1].

HEART TRANSPLANTATION

The United Network for Organ Sharing (UNOS) is a nonprofit organization that maintains the nation’s organ transplant waiting list. Patients awaiting cardiac transplantation are listed according to severity of illness. Organs are then allocated to those individuals who are most ill and have waited the longest. The waiting list for heart transplant has steadily grown because more patients are added than removed every year. The most current UNOS summary was published in 2012. The UNOS wait-list has approximately 3,000 patients awaiting transplant. Subsequently, the number of heart transplants has been increasing since 2004, with roughly 2,500 performed annually in the United States. Wait-list times peaked in 2007 and since then have decreased. The average wait-list time for status 1A candidates is 2.4 months, status 1B candidates
is 6.9 months, and status 2 candidates is 20 months [2]. Status 1 heart candidates have the highest medical urgency. These are patients who have support either via a total artificial heart, ventricular assist device (VAD), intra-aortic balloon pump, or extracorporeal membrane oxygenation. It could also be an individual who has a mechanical assist device in place and either right or left ventricular support that is beginning to malfunction. It also includes individuals who are on continuous mechanical ventilation or on high-dose inotropic support that cannot be weaned. Status 2 candidates are individuals who need heart transplantation but have not been defined as being in the most urgent status. These patients typically are at home, still active, and taking heart-failure medications while awaiting transplantation.

The annual mortality rate on the waiting list has continued to decline over the last 10 years. In general, pretransplant mortality declined from 15.8 deaths per 100 wait-list years in 2002 to 12.4 in 2012 [2]. This slow decrease is related to the evolution of left ventricular assist devices (LVADs) and their acceptance as a bridge to heart transplantation.

In 2012, 54.0% of transplants were performed for cardiomyopathy, 32.8% in patients with coronary artery disease, and 9.9% in patients with congenital heart disease. The number of transplantations increased for patients with cardiomyopathy and congenital heart disease, 34% and 28%, respectively. The number of transplantations in patients with valvular heart disease decreased 44%. In 2012, 41.3% of patients had prior VAD support. Cardiac retransplantation represents approximately 4% of the adult heart transplant population annually. Most patients who received a transplant had private insurance; however, the proportion of insured versus those on Medicare decreased between 2002 and 2012 [2].

### Patient Selection

Many of the specific critical care problems seen in thoracic organ recipients can be reduced by careful patient selection. In well-compensated patients, a week-long outpatient evaluation is performed. This applies to approximately 80% to 90% of patients seen at a cardiac transplant center. The other 10% to 20% are individuals who are critically ill and undergo an urgent transplant evaluation.

The recipient assessment consists of a general evaluation, an assessment of the functional and hemodynamic status, and a psychosocial evaluation. All parts are equally crucial. One of the first assessments is an oxygen-consumption treadmill test. For those patients who are capable of performing this test, there are excellent data which demonstrate that a peak oxygen consumption of less than 12 mL/kg/min is associated with a very poor 1-year survival rate without transplant. Individuals with a peak oxygen consumption of less than 15 mL/kg/min
should be considered for listing [3,4]. The assessment then proceeds with a general evaluation. The patient’s medical history is examined to try to determine the cause of the patient’s heart disease. General laboratory tests are performed, including a creatinine clearance. Individuals who have a creatinine clearance of less than 50 mL per minute do have a significant increase in the need for postcardiac transplantation dialysis and have lower rates of survival than those with near-normal renal function. Individuals with severely abnormal creatinine clearance would be excluded from heart transplant or considered for heart-and-kidney transplantations. Individuals with diabetes need further end-organ evaluation prior to listing to understand the full scope of their risk.

Nutritional status is also crucial. Those individuals with a body mass index (BMI) less than 20 kg per m² or greater than 35 kg per m² would be asked to either gain or lose weight, respectively. Again, individuals at the extremes of the body mass index have higher rates of mortality in the postoperative period than those with normal BMI [5,6].

The hemodynamic evaluation consists of an echocardiogram to evaluate function and anatomy, and a cardiac catheterization. The cardiac catheterization includes evaluation of heart function by a right heart catheterization as well as a coronary angiogram. In this assessment, the patient’s coronary anatomy is examined for potential intervention, and any abnormalities in the filling pressures, pulmonary capillary occlusion pressure, or pulmonary vascular resistance are identified.

Patients with heart failure and secondary pulmonary hypertension are a group who are of special interest. Pulmonary arterial and capillary wedge pressures are measured to determine the degree to which a patient has secondary pulmonary hypertension and whether or not it is reversible. The patient’s hemodynamics should be optimized in the catheterization laboratory in an attempt to decrease the pulmonary arterial pressures to normal levels, and 100% oxygen, nitric oxide, and other pulmonary vasodilators can be used to test the reactivity of the pulmonary vasculature. The absolute exclusion criteria for heart transplantation are a pulmonary vascular resistance greater than 4 Wood units (WU) and, more importantly, a transpulmonary gradient greater than 15 mm Hg. Individuals with values outside these values would then be listed for heart–lung transplant, or be given a trial of pulmonary vasodilators.

The patient’s ABO blood type and panel-reactive antibody (PRA) level are determined to quantitate the patient’s preexisting antibodies and sensitization to the general population. If class II (locus D) is greater than
20%, it is recommended that a preoperative crossmatch be performed. The patient’s HLA typing is also done at that time, and if the PRAs are significantly elevated, the laboratory should be able to identify the particular human leukocyte antigen to which the individual is reacting. Sensitization can occur in many situations. It may occur because of pregnancy, between sexual partners, from prior transplantation, or with transfusions often associated with the placement of a VAD. Individuals who carry a high PRA level have been treated in the past with plasmapheresis, intravenous immunoglobulin, cyclophosphamide, and mycophenolate mofetil (MMF). There have been inconclusive results with each of these. Recent studies from a nationwide sample of the UNOS database demonstrated that ABO-compatible versus ABO-identical transplantation recipients did not have significant differences in survival rates [7].

The psychosocial evaluation should be centered on evaluating not only the transplant recipient, but also the family support for the patient. This needs to be performed by a qualified professional experienced in social work and, when indicated, other mental health professionals who have a keen understanding of the demands made on a postoperative cardiac transplantation patient. Patients need to be medically compliant, have adequate neurocognitive function for the postoperative regimen, and adequate social support.

Once the evaluation has been completed, the patient is evaluated for any relative or absolute contraindication for heart transplantation. Those relative contraindications include: age greater than 70 years, previous chronic substance abuse, limited social support, limited adaptive ability, mild renal dysfunction, active peptic ulcer disease, cachexia, obesity, and cigarette smoking. It should be noted that to receive a heart transplantation, individuals who smoke are required to go through a smoking-cessation program, and many transplant programs require them to sign a contract stating that they will not resume smoking prior to or after the transplantation. They also are evaluated for chemical evidence of smoking during their waiting time [8].

Absolute contraindications to cardiac transplantation include: ongoing substance abuse, refractory psychiatric conditions, suicidal behavior, severe personality disorder, issues with ongoing medical noncompliance, inadequate neurocognitive ability, irreversible hepatic or renal dysfunction, severe peripheral or cerebral vascular disease, systemic disease that limits rehabilitation, insulin-dependent diabetes with severe end-organ damage, or evidence of severe, fixed, secondary pulmonary hypertension [8–10].

**Implantable Cardiac Assist Devices**
VADs represent the greatest advance in the treatment of end-stage heart failure and the field of heart transplantation in the past 10 years (Table 60.1). With an assist device implanted, patients who would otherwise not survive long enough to receive a heart transplantation are now living independently at home with reasonably good quality of life until a suitable organ becomes available. As of 2012, 35.6% of transplant recipients were using an LVAD at the time of operation. This has impacted the number of patients reliant on inotropes at the time of transplant, with a decrease from 43.4% in 2007 to 36.2% in 2012 [2,11].

From their increased use, a corpus of terminology has evolved to categorize and describe the devices themselves, their use, and technical aspects of their function and performance. Most devices are designed to assist the left ventricle and hence are called LVADs. However, some models are made to be implanted in either ventricle and when implanted on the right side are referred to as a right ventricular assist device (RVAD). When both ventricles are mechanically assisted, each with its own pump, the whole system together is referred to as a biventricular assist device, or BIVAD.

There are two broad categories of devices in use based on pump mechanism: pulsatile devices that employ some type of pneumatic pump, and continuous, or axial flow devices that involve a spinning propeller. The cycles of the pulsatile device are measured in beats per minute (bpm) and that of the continuous-flow pumps in revolutions per minute (rpm).
Each device has an inflow cannula through which the patient’s blood is drawn from the heart and into the pump and an outflow cannula that directs the blood back into the patient’s circulation.

For both pulsatile pumps and continuous-flow pumps, there are two more classifications that can be described on the basis of the location of the pump when implanted: intracorporeal, wherein the entire pump is implanted inside the body with the exception of the drive-line that powers the device and passes through an exit site on the abdomen; the other is paracorporeal, or extracorporeal, wherein the pump sits outside the body and the inflow and outflow cannulae enter and exit the skin on the upper abdomen just below the costal margin. Most LVADs usually involve an inflow cannula placed in the apex of left ventricle and the outflow cannula in the ascending aorta.

The only permanent RVAD approved for use in the United States is the Thoratec Paracorporeal VAD and its inflow cannula is placed in the right ventricular free wall and the outflow cannula is anastomosed to the pulmonary artery. The Levitronix CentriMag (now owned by Thoratec) is approved for temporary right ventricular assistance up to 30 days and its inflow cannula may be placed in either the right atrium or the right ventricle.

Devices are categorized based upon the intended therapeutic goal for each particular patient. Bridge to transplant (BTT) indicates that the patient is or will become a heart transplant candidate and the device is intended to improve survival and other physiologic parameters until an organ is available. Destination therapy (DT) indicates that the patient is not a transplant candidate but the device is implanted to improve survival and quality of life for the remainder of the patient’s life. Bridge to recovery refers to the patient who is expected to recover from heart failure and the device is used to sustain life until the time when it can be weaned off and explanted. Bridge to decision (BTD) refers to those patients for whom survival is not certain and a temporary assist device, such as the AbioMed BVS5000 or the Levitronix CentriMag, is used in the critical care setting to prolong life until it can be determined whether the patient ought to be implanted with a long-term device as those used in BTT or DT patients or be disconnected from the BTD device and allowed to expire.

The superior efficacy of VADs over optimal medical management in improving survival in end-stage, New York Heart Association Class 3 or 4 heart-failure patients was proven in the REMATCH trial: patients implanted with the Thoratec HeartMate VE had a 52% survival at 1 year compared to 25% in the medically managed group \[12\]. Subsequently, the Food and Drug Administration (FDA) approved the HeartMate XVE for DT. The Thoratec HeartMate II continuous-flow pump demonstrated efficacy in bridge to transplantation with 75% survival at 6 months.
postimplantation and 68% survival at 1 year [13]. It received approval by the FDA in April 2008 for bridge to transplantation and was subsequently approved for DT in January 2010. Smaller devices such as the Jarvik 2000 Flowmaker and the HeartWare VAD are currently under investigation in the United States with more than two dozen other devices presently in development (Fig. 60.1).

Knowing how these devices work and how these patients are managed will be an important part of the pretransplantation care of the recipient. Almost all of these patients will present anticoagulated on warfarin. It will be important not to begin administration of plasma and cryoprecipitate until the plan to proceed with the transplant is certain. Administration of blood products without completing the transplantation will only sensitize the recipient and increase the PRAs for any subsequent transplant offers [14]. The postoperative course is often complicated by bleeding. Drains for the VAD pocket are necessary and pericardial effusions are common.

Several studies have examined posttransplant survival and recent studies have shown that recipients of VADs have had equivalent or better posttransplant outcomes [15,16]. One exception is the patient who had VAD-related sepsis prior to transplantation, as these patients had a trend to slightly poorer posttransplantation rates of survival than those patients who did not have an infection [17].

**Donor Criteria**

The donor evaluation begins with the pronouncement of brain death. The local organ-procurement agency will obtain consent for donation from the family and proceed with the donor evaluation and support. The donor evaluation consists of taking a general history of any illnesses or risk
factors such as heart disease, hypertension, diabetes, or cigarette smoking. Specifics are gathered surrounding the time and mode of death to determine whether there is any potential cardiac injury, down time, cardiopulmonary resuscitation, or cardioversion. The organ-procurement professionals will proceed with a hemodynamic evaluation of the patient. This consists of measuring central venous pressures and, potentially, full hemodynamic profiles if pulmonary artery catheter measurement capability exists at the hospital caring for the donor. Once the donor is stabilized hemodynamically, further studies are performed. The initial stabilization phase should include endocrine support with the administration of levothyroxine and corticosteroids, reduction of inotropic support if it is appropriate, and, potentially, diuresis or transfusion when indicated. A surface echocardiogram is then performed to make sure the heart is structurally normal and that function is normal. A 12-lead electrocardiogram is also obtained. It is not uncommon to find subtle ST changes in individuals who are brain-dead. It is generally accepted that a cardiac catheterization will be necessary in male donors more than 40 years old and female donors more than 45 years old, but catheterization should also be performed in younger donors when the donor has a significant history of hypertension, cigarette smoking, diabetes, or alcohol abuse. Cardiac enzymes need to be carefully evaluated and correlated to any severe hemodynamic instability, the use of cardiopulmonary resuscitation, as well as the time of herniation [18].

A number of studies have demonstrated correlations between elevations of troponin and early graft failure [19,20]. In one study, a cardiac troponin I value greater than 1.6 \( \mu \)g per L was a predictor of early graft failure, with a sensitivity of 73% and a specificity of 94% [19]. These data should be analyzed closely with the patient’s hemodynamic function and echocardiographic findings.

A transplant center may request that a second echocardiogram be performed if the first echocardiogram was performed shortly after herniation. Catecholamine-induced left ventricular dysfunction can improve significantly in a short period of time and not preclude excellent short-and long-term outcomes. One must also take into consideration the ischemic time that will be incurred with procurement and travel time. The majority of transplant centers are willing to accept an ischemic time up to 4 hours for adult donors but no more than 6 hours.

The advent of ex vivo perfusion offers the possibility of warm perfused preservation of thoracic organ grafts. The technology is currently commercially available in Europe and is under FDA investigation in the United States. Ex vivo perfusion uses warm oxygenated blood and an extracorporeal pump to perfuse organs during transport and preservation. This technology offers the potential for longer extracorporeal periods and possibly altering the paradigm of cold
preservation. The Organ Care System designed by TransMedics (Boston, MA) and Perfusix (Toronto, CA) are two examples of ex vivo perfusion. The PROCEED II trial was a noninferiority study confirming that OCS warm perfusion versus cold-storage in heart allografts was comparable in 30-day patient and graft survival [21].

Operative Techniques

Donor Operation

Once the donor has been prepared and the abdominal team has started their procedure, the median sternotomy incision is performed. If lungs are being harvested, both pleural spaces are also opened for inspection of both lungs. During this inspection, one should palpate the coronary arteries to discern any calcifications and also palpate the aortic root for calcifications. External evaluation of the heart is not a reliable evaluation of function unless there is something grossly abnormal, such as severe bruising from a myocardial contusion or a dilated right ventricle. Once it is determined that the heart is appropriate for transplantation and all of the other organ teams are ready, the donor is heparinized and cannulated. The heart is cannulated with a cardioplegia cannula in the ascending aorta. If the lungs are being harvested, a pulmonary artery cannula will be placed in the main pulmonary artery. Once all teams are ready, the aorta is cross-clamped and the flush solution is given. Between 1 and 2 L of cold cardioplegic solution is administered. The heart is vented via the left atrial appendage, excised, and is then submerged in ice slush saline, packaged steriley, and placed in a cooler for rapid transport to the center caring for the recipient.

Recipient Operation

Once the recipient is prepared and draped, the median sternotomy incision is made and the heart is dissected free of any adhesions, and then cardiopulmonary bypass is established. The recipient is placed on total cardiopulmonary bypass, before the cross-clamp is applied to the aorta, and the heart is excised along the atroventricular groove. The great vessels are divided just above their respective semilunar valves. The anastomoses are performed in the following order: left atrial, inferior vena caval, pulmonary arterial, aortic, and superior vena caval [22]. Temporary pacing wires are left on the
donor right atrium and right ventricle. The organ is reperfused and, once it has recovered, is separated from bypass. On separation from bypass, appropriate inotropic support is administered. Typically, the patient may require dopamine or epinephrine and milrinone for postoperative support. Isoproterenol is used to maintain an appropriate heart rate if bradycardia is a problem or the heart is paced. The pulmonary artery catheter should be floated through the new heart so that pulmonary artery pressures can be monitored closely and any signs of right heart failure can be detected early.

**Postoperative Care**

The immediate postoperative management of a heart transplant recipient is by and large not unlike that of other cardiac surgery patients. Drips and temporary pacing leads are modified to optimize cardiac index and end-organ perfusion. Typical inotropes used are epinephrine, dopamine, dobutamine, and milrinone. A pulmonary artery catheter is used with continuous mixed venous oximetry and preload is optimized with either volume or diuretic. Usually patients come out of the operating room on Isuprel (isoproterenol) to stimulate the heart rate and/or the temporary pacemaker set to a back-up rate of 90 to 100 bpm or higher. The ideal heart rate for these patients in the first few days postoperatively is 100 to 120 bpm. After the first several days, the heart rate is allowed to drift to its baseline as the cardiac index allows. Occasionally, patients exhibit a distributive shock immediately postoperatively characterized by low systemic vascular resistance and vasopressin or neosynephrine is used to treat it.

Ventilatory management varies from patient to patient. The ideal patient who is hemodynamically stable and has no signs of surgical bleeding can be extubated within a few hours. Sometimes, patients with right ventricular failure owing to pulmonary hypertension need to be treated with inhaled nitric oxide or epoprostenol (Flolan) and thus mechanical ventilation is continued.

Patients who have had a VAD placed as a bridge to transplantation frequently have had two or more prior sternotomies and arrive at the hospital on Coumadin. These patients have a tendency to bleed more postoperatively and one should keep a low threshold to return to the operating room for exploration if bleeding persists.

Serious ventricular failure after cardiac transplantation is unusual and can be related to poor donor-organ selection, poor graft preservation, a long ischemia time, or rejection owing to the presence of preformed antibodies. Early rejection is often heralded by atrial fibrillation and the manifestation of arrhythmias should prompt an immediate workup and treatment. Plasmapheresis can be very effective in removing preformed
antibodies responsible for humoral rejection. Inotropes and pulmonary vasodilators are also often used to manage the right heart failure that frequently accompanies rejection, with the addition of an intra-aortic balloon pump if necessary. In cases of severe graft dysfunction, VADs can support the patient until either the donor heart recovers or retransplantation takes place.

Immunosuppression

Balanced triple-drug immunosuppression is still the most commonly used protocol, consisting of calcineurin inhibitors, an antimetabolite, and corticosteroids (Table 60.2). The calcineurin inhibitors include cyclosporine and tacrolimus. Cyclosporine is largely recognized as the agent that moved cardiac transplant from a feasible medical option to an acceptable medical treatment. The physicians at Stanford University performed a randomized controlled trial in cardiac transplant patients that demonstrated that cyclosporine immunosuppression improved 1-year survival to 80% from the mid-50% range [23]. Patients receiving either cyclosporine or tacrolimus have similar survival rates in heart transplantation, both long and short term [24–26]. However, in a controlled clinical trial by Kobashigawa et al. in 2006, studying 343 de novo cardiac transplant patients, tacrolimus in combination with either mycophenolate or sirolimus had fewer occurrences of grade 3 A or greater rejection or hemodynamic compromise rejection at 1 year when compared to cyclosporine and mycophenolate [27]. In addition, median serum creatinine and triglyceride levels were lowest in the tacrolimus and mycophenolate group. Cyclosporine is well known to also cause postoperative hypertension, nephrotoxicity, hepatotoxicity, gingival hyperplasia, hypertrichosis, and tremor. Tacrolimus also causes nephrotoxicity and many of the other side effects of cyclosporine but to a lesser extent, in particular, posttransplant hypertension and gingival hyperplasia. A review article from Stanford confirmed improved survival with the use of tacrolimus and improved postoperative infection prophylaxis [28].

The antimetabolites include MMF and azathioprine. These inhibit purine synthesis and thus block the proliferation of both T and B cells. They are complementary to the calcineurin inhibitors. Kobashigawa et al. [29] demonstrated considerable benefits to MMF over azathioprine when coupled with cyclosporine in transplants performed in 1998. MMF is currently the most widely used antimetabolite in heart transplantation [26].

Corticosteroids remain a cornerstone of therapy. There are multiple regimens for early corticosteroid reduction to avoid the serious associated side effects including systemic hypertension, obesity, osteoporosis, and glucose intolerance. In spite of the negative side effects, in 2004, approximately 75% of patients were still taking corticosteroids 1 year following their transplants [30]. Monotherapy consisting of tacrolimus is currently being studied in heart transplant recipients. In one study, 75% of recipients were successfully converted to monotherapy [31]. Results from the group at Stanford confirm that therapy with tacrolimus and limited corticosteroid are linked to improved recipient and graft survival [28].

The use of IL-2 receptor blockade has become more prevalent during the last 4 to 5 years. These proliferation signal inhibitors, sirolimus and everolimus, block the activation of the T cell by binding the IL-2 receptor. They have shown promise in significantly reducing the severity of cardiac allograft vasculopathy, the main threat of long-term graft survival. But they remain only an adjunct to the calcineurin inhibitors that are still more effective in preventing acute rejection.

Outcomes

The Registry of the International Society for Heart and Lung Transplantation (ISHLT) has reported on survival after cardiac transplantation in adult patients. Survival rates have increased from 89% in 2008 to 94% in 2014 at 1 year [32]. The UNOS/OPTN (Organ Procurement and Transplantation Network) database also reported
survival rates for the years 2005 to 2007 of 88% at 1 year, 81% at 3 years, and 75% at 5 years. UNOS notes that survival rates are lowest among the patients 18 to 34 years of age [2].

Over the years, the average survival rate for cardiac transplant patients improves. The median survival in patients who were transplanted between 1982 and 1988 was 8.1 years, and that has increased to 9.8 years for individuals transplanted between 1994 and 1998. A significant improvement that has occurred during the current era is the 1-year survival for cardiac retransplantation, which is markedly better than that reported in past eras. The 1-year survival for these patients is 82.4% [2].

General Complications of Heart Transplantation

Right Heart Failure and Pulmonary Hypertension

Frequently acute right heart failure in the postoperative heart transplant patient is secondary to pulmonary hypertension. As mentioned, patient selection is crucial in identifying those recipients with fixed pulmonary hypertension. Those with a pulmonary vascular resistance ≥4 WU, a systolic pulmonary artery pressure ≥60 mm Hg or a transpulmonary gradient ≥15 mm Hg that does not reverse with vasodilator therapy such as inhaled nitric oxide or a prostacyclin analogue such as epoprostenol should not receive a heart transplant. Despite this, there are still recipients who will have some degree of pulmonary hypertension that will cause right heart strain posttransplantation.

Though right heart failure is frequently accompanied by pulmonary hypertension, other causes include donor selection, poor preservation, or prolonged ischemia time. The main principles of management in all cases of right heart failure are to preserve coronary perfusion, optimize RV preload, and reduce afterload by using high inspired oxygen concentrations, inhaled nitric oxide, and/or prostacyclin [33]. Intravenous milrinone or dobutamine followed later by oral sildenafil are also mainstays of therapy. Finally, in severe cases of right heart failure in the acute postoperative setting, a temporary right VAD is used to bridge the heart to recovery. The need for mechanical assistance typically lasts only a few days to a week and a low threshold should be kept for implanting a device.

Rejection
Surveillance for rejection of the transplanted heart by evaluating endomyocardial biopsies of the right ventricle obtained via the right internal jugular vein is performed frequently during the first year and eventually lessens to two to three times per year. There are four types of rejection: hyperacute, acute cellular, acute humoral, and chronic. The grading scale for rejection was recently revised to simplify it and also because there appeared to be little clinical difference between grade 1A and 1B rejection in the old classification. There was evidence of a benign clinical course for grade 2 rejection in the old classification as well [34]. The new grading system is shown in Table 60.3.

The mainstay of treatment is pulse corticosteroids administered intravenously for 3 days, with or without a subsequent taper. In the case of hemodynamically significant rejection or suspected acute humoral rejection, ultrafiltration, and intravenous immunoglobulin are administered to lower circulating antibodies. The addition of methotrexate or cyclophosphamide also should be considered. Photopheresis has been used to treat patients who have preexistent high levels of PRAs [35]. Late chronic rejection manifests as cardiac allograft vasculopathy. It is thought to be owing to a combination of humoral and cellular rejection, and is the greatest threat to long-term survival. When a patient has no other options to treat chronic, unrelenting rejection, the last resort is retransplantation.

**Infection and Pneumonia**
Patients who have undergone thoracic organ transplantation are susceptible to bacterial, fungal, and viral infections. The most morbid viral infection that occurs in thoracic organ transplant recipients is caused by cytomegalovirus (CMV) [36]. Transmission of CMV by a donor organ is very common and hence prophylaxis with ganciclovir is used in CMV-mismatched thoracic transplant recipients. Patients who are seronegative at the time of transplantation and receive a graft from a seropositive donor sustain the highest rate of infection and exhibit the most severe form of CMV disease. Ganciclovir is the treatment of choice.

Pulmonary complications occur in approximately a third of heart transplant recipients [36,37] and is the most common infectious complication in heart transplant recipients. In the first 6 months, hospital-acquired bacterial pneumonia is the most common pulmonary complication followed by Aspergillus pneumonia. The overall mortality associated with pneumonia is 35% to 55% and accounts for 40% of all-cause mortality. A heightened vigilance for pulmonary infection is critical and the presence of yeast or mold-positive sputum should be aggressively treated. Risk factors for pulmonary complications are older recipient age, moderate-to-severe rejection, and development of CMV antigenemia in a previously CMV-seronegative recipient [36].

**Coronary Allograft Vasculopathy**

The development of coronary allograft vasculopathy can lead to myocardial infarction and sudden death in the cardiac transplant recipient. Routine annual coronary angiography with intravascular ultrasound is performed to permit an accurate assessment of the time of onset and rate of progression of coronary artery disease. Graft atherosclerosis occurs in 30% to 40% of transplant recipients after 3 years and in 40% to 60% of patients by 5 years after transplantation [38]. It remains the major obstacle to long-term survival in cardiac transplant recipients. A correlation between CMV infection and accelerated allograft atherosclerosis has also been identified [39]. Immunologically-mediated endothelial damage has been proposed as a stimulus for the development of graft atherosclerosis. Treatment can be temporizing in the form of angioplasty for focal lesions; however, when the disease involves tapering of the distal vessels, only cardiac retransplantation can treat the problem.

**Renal Failure**

Renal failure in the perioperative period is often transient, and it may be the direct result of nephrotoxic immunosuppressive drugs. Mild impairment of renal function preoperatively is acceptable as long as the risk of severe renal impairment during the postoperative period is
recognized as a possible complication. The lowest acceptable level for creatinine clearance in a potential thoracic organ transplant recipient is 50 mL per minute. For suitable patients, combined heart-and-kidney transplant can be considered. It is also possible for a patient to be listed for a kidney transplant following thoracic organ transplantation.

Posttransplant Lymphoproliferative Disease

Posttransplant lymphoproliferative disease is a common cause of late death following solid-organ transplantation. It is more commonly seen in the pediatric population and is associated with exposure to the Epstein–Barr virus (EBV). Those at greatest risk for posttransplant lymphoproliferative disease are individuals who are EBV-seronegative before transplant who convert after their transplant. Those individuals who are EBV-seropositive before transplant are at a lower risk, but are not risk free. Management includes vigilant monitoring of the patient’s EBV status, EBV polymerase chain reaction testing, and regular examinations of lymph node beds for enlargement. Therapy once this problem occurs has not been standardized and includes the use of antiviral agents, reduction of immunosuppression, anti-CD20 antibodies (such as rituximab), chemotherapy, and radiation therapy. Many of these have been used in combination.

Gastrointestinal Problems

Approximately 40% of patients experience gastrointestinal complications posttransplantation. The majority are related to drug side effects, most notably MMF that can cause nausea, vomiting, and diarrhea [40]. These are most often managed with dose adjustments. Serious complications of the alimentary tract following heart and heart–lung transplantation have been well documented and remain a major source of morbidity and mortality [41]. For that reason, patients with active peptic ulcer disease or diverticular disease are not considered for thoracic organ transplantation, at least until these problems have resolved. Mild liver dysfunction as evidenced by elevation of serum transaminase values and hyperbilirubinemia may occur in patients receiving high doses of cyclosporine. This is a chemical hepatitis that usually responds to a decrease in the dosage. Other immunosuppressants such as azathioprine have been implicated in a similar process. Hepatitis may also be secondary to hepatitis B, CMV, herpes simplex virus, hepatitis A, or hepatitis C.
Biliary tract disease is common in the thoracic organ transplant population. In a series of heart transplant recipients, the incidence of cholelithiasis ranged from 30% to 39%, which is more than twice that expected for age- and gender-matched controls [42]. The primary cause of this problem is thought to be gallbladder stasis and the side effects of specific immunosuppressants [43].

Cardiac Retransplantation

Cardiac retransplantation represents a small fraction of the transplants that are performed annually (the UNOS/OPTN database: 3% to 5% annual retransplant rate) [2]. According to the ISHLT database, approximately 2% of all adult heart transplantations internationally are retransplants. In the pediatric heart transplant population, this rate is approximately 6% of all transplantations. Current 1-year survival for heart retransplant is 82%, closely approaching the 1-year survival of the original transplantation [44]. The primary indications for retransplantation appear to be early graft failure, and in later time periods, chronic rejection or graft atherosclerosis.
HEART–LUNG TRANSPLANTATION

Heart–lung transplants are performed almost exclusively in patients with surgically uncorrectable congenital heart disease and Eisenmenger physiology. Patients with unrelated severe cardiomyopathy and pulmonary disease may also be candidates for heart–lung transplantation. With the difficulty of obtaining a heart–lung block and the outcomes of these procedures, many surgeons repair the congenital heart defect and transplant only the lungs [45,46]. Increasing numbers of patients with primary pulmonary hypertension are being treated with bilateral single-lung transplant rather than with heart–lung transplantation.

There has been a constant decline in the number of heart–lung transplants performed since the mid-1990s, both nationally and internationally, with fewer than 90 heart–lung transplants being performed annually in the current era [2].

Donor Criteria and Organ Procurement

The donor criteria are similar to the criteria used for heart (as listed previously) and lung transplantation (see Chapter 59). The procurement of the heart–lung block entails simultaneous use of techniques that are otherwise used to procure these same organs separately.

Operative Technique

From the outset, the recipient is placed on cardiopulmonary bypass. The recipient heart is excised first, and then each lung is removed. The phrenic neurovascular bundles are protected bilaterally. The left recurrent laryngeal nerve is also at risk for damage in the region of the ligamentum arteriosum. For that reason, some surgeons leave a portion of the main and left pulmonary artery in situ. The tracheal anastomosis is performed first. Although it can be wrapped with omentum, it does not need to be, because the coronary–bronchial collateral circulation is generally excellent. Performance of the right atrial anastomosis or bicaval anastomoses is followed by the aortic anastomosis. Large aortopulmonary collaterals and bronchial vessels can develop in patients with chronic cyanosis and Eisenmenger physiology. Extreme care must be taken during the operative procedure in these patients to avoid postoperative bleeding.

Postoperative Care
Postoperative care of patients who have had heart–lung transplantation can be quite complex. Potential complications from the heart or the lungs can arise. The standard postoperative care most closely resembles that of a lung transplantation patient, and is discussed in Chapter 59. Postoperative bleeding can be quite profound in this subset of patients, even with careful operative control of collateral vessels.

Outcomes

As of 2009, the current registry reports from ISHLT demonstrate a 1-year survival rate of only 75% for individuals undergoing a heart–lung transplantation. The average survival for this group of patients who were transplanted between 1982 and 2003 was 3.2 years. Because of the significant mortality rate that occurred within the first year after the transplantation, the conditional half-life was higher at 9 years [30]. Early mortalities were owing to technical complications, graft failure, and non-CMV infections accounting for 73% of the deaths. Mortality that occurred beyond the first year was attributed to chronic lung rejection with bronchiolitis obliterans, whereas cardiac rejection or coronary vasculopathy played a minimal role.

In the field of heart–lung transplantation, it was initially thought that endomyocardial biopsy would be the appropriate diagnostic test to detect rejection [47,48]. However, with two organ systems involved, the lungs often reject despite normal findings on endomyocardial biopsy [45]. Transbronchial biopsy reveals what is occurring in the lungs during the perioperative period and, later, complications in the lung grafts may be suggested when there are changes on chest radiograph or in pulmonary function studies, and should be evaluated with transbronchial biopsy [49]. Treatment of recurrent lung rejection consists of pulse corticosteroids with or without a taper. Alternate therapies including lympholytic agents, photopheresis, methotrexate, or cyclophosphamide may be used for refractory cases of rejection [50].
CONCLUSION

The discipline of heart transplantation has recently passed its 40th anniversary, and many major advances have been made. In spite of the changes that have occurred in recipient criteria, the greater number of potential recipients coming to transplant who are more than 60 years of age, on inotropic support, or using mechanical assist, the outcomes of heart transplantation have improved with each passing year. The field has also enjoyed seeing a decrease in candidate waiting times on the list and the evolution of cardiac assist devices to improve candidates for heart transplant. Clearly, knowledge of cardiac transplantation is directly related to the duration of experimental and clinical experience. It is expected that, as understanding continues to expand, long-term survival of transplant recipients will increase.
REFERENCES

Type 1 diabetes mellitus has two primary treatment options: (a) exogenous insulin administration or (b) β cell replacement by pancreas or islet transplantation. Despite the introduction of many new and improved modalities for insulin administration, exogenous administration requires complex and frequent monitoring and responsiveness from the patient, making it burdensome. Often, patients face a choice between imperfect glycemic control, predisposing them to secondary complications including retinopathy, neuropathy, and nephropathy, or too tight control possibly precipitating hypoglycemic unawareness, which can dramatically impact quality of life.

Pancreas and islet transplantation when successful produces a more physiologic euglycemic state and effectively treats hypoglycemia episodes. However, pancreas transplantation requires major surgery in which perioperative risks are often compounded by the comorbidities frequently seen in patients with long-standing diabetes. Additionally, the long-term effectiveness of islet transplantation continues to be a challenging goal. Moreover, both require long-term immunosuppression to prevent rejection, resulting in increased risks of infection and cancer.

In 1993, The Diabetes Control and Complications Trial [1] showed that intensive insulin therapy (multiple injections per day with doses adjusted by frequent blood sugar determinations) resulted in a 60% reduction in the risk of secondary complications despite typically failing to achieve normalization of glucose [2]. Current American Diabetes Association (ADA) guidelines recommend multiple-dose insulin injections (three to four injections daily of basal and prandial insulin) or continuous subcutaneous insulin pump with the goal of achieving an HbA1C <7% and <6.5% when risks of hypoglycemia or other adverse effects are low [3].
National Health and Nutrition Examination Survey (NHANES) data show that almost half (45%) of patients failed to achieve glycemic targets (HbA1C < 7%) [4].

Pancreas transplantation can produce insulin independence in diabetic recipients, decrease risks of life-disabling hypoglycemia, and slow progression and even reverse secondary complications including retinopathy, nephropathy, and neuropathy [5]. With major advances in technical aspects and management of pancreas transplantation, the success rate has progressively increased since its introduction. Currently, 1-year patient survival is 95% after pancreas transplantation [6]. One- and five-year pancreas graft survival was 74% to 78% and 51%, respectively, for pancreas transplant alone; 86% and 74%, respectively, for simultaneous pancreas–kidney transplantation; and 79% to 80% and 62%, respectively, for pancreas after kidney transplantation [6,7]. Today’s recipients have a high probability of achieving insulin independence for years with pancreas transplantation, if not indefinitely.

Historically, islet transplantation has had lower rates of insulin independence than pancreas transplantation. In the late 1990s at the University of Alberta, insulin independence was achieved by sequential transplantation of islets from multiple donors and the use of a steroid-free, nondiabetogenic, immunosuppressive regimen [8]. In another series from the University of Minnesota with a similar immunosuppressive regimen, single-donor islet transplantation induced insulin independence [9]. In this series, the donors had a high body mass index (BMI) and the recipients had a low BMI so that the net number of islets transplanted per unit weight was similar in the Alberta and Minnesota series. In subsequent follow-up under the Edmonton protocol, 68% (44/65) of patients who received one to three islet transplants achieved insulin independence [10]. However, at 5-year follow-up, only 10% maintained insulin independence with a median duration of insulin independence of 15 months (interquartile range 6.2 to 25.5) [11]. Although outcomes with islet transplantation have improved, pancreas transplantation continues to provide higher rate of more durable success.

The main trade-off for recipients of β-cell allografts is the need for immunosuppression. A successful graft makes the recipient euglycemic and normalizes glycosylated hemoglobin levels, but the combined risks of immunosuppression and a major pancreas transplant surgery must be weighed against the long-term risks of imperfect glycemic control with exogenous insulin injection and of development of secondary complications. A randomized prospective trial has not been done to weigh these risks. The burden of daily management of diabetes with the need for multiple sticks to monitor blood sugar levels and to inject insulin tilts the balance in favor of a pancreas or islet transplant for many diabetic patients. Furthermore, antirejection strategies are continually
being modified to decrease the complications of immunosuppression. Nevertheless, pancreas transplantation is more frequently performed later in the course of disease often after the recipient has become uremic and needs a kidney transplant. Currently, only 12% of pancreas transplantations are performed alone before the onset of end-stage renal disease [7].

The main indications for pancreas transplantation in patients with normal kidney function are progressive diabetic complications, glycemic lability, and hypoglycemic unawareness, the latter of which may emerge years after the onset of diabetes, particularly in patients with autonomic neuropathy. However, even for nonlabile diabetic patients who attempt tight control by intensive glucose monitoring, the diabetes literature shows a high rate of secondary complications that are just as morbid, balancing out the risks associated with chronic immunosuppression in pancreas transplantation recipients [12]. Given that most pancreas transplantation candidates have advanced diabetic nephropathy and require a kidney transplant also, the risks of immunosuppression are already assumed because of the kidney transplant, and so a simultaneous or sequential pancreas transplant does not pose significant additional risks other than those associated with surgery [13]. Although most pancreas transplantations are performed in type 1 diabetics with impending or chronic renal failure, some pancreas transplantations are performed in patients categorized as having type 2 diabetes [14]. Currently, approximately 7% of pancreas transplantations annually in the United States are performed in type 2 diabetics [7]. Many reports have shown successful outcomes with comparable survival rates as seen in type 1 diabetics [15,16]. There has been much controversy surrounding the increasing use of pancreas transplantation for type 2 diabetes and wide variability in the definitions used to categorize patients as type 1 versus type 2 diabetics and as such United Network of Organ Sharing (UNOS) has set strict guidelines regarding recipient BMI criteria in patients with detectable C-peptide levels (>2 ng per mL) in order to accrue waiting time [17].

While β-cell replacement therapies are ideal for type 1 diabetes management, this approach suffers from a lack of available suitable donors. Thus, stem cell–based therapies have the potential to make β-cell restoration possible, for both forms of diabetes. In addition to β-cell replacement, the use of mesenchymal stromal cells may modulate autoimmunity and promote regeneration of the recipient’s islet cells [18]. Previous attempts at in vitro stem cell therapy for insulin production lacked uniformity in the generation, maintenance, and differentiation of β cells [19]. Recent advances in understanding pancreatic development in the mouse have led to considerable progress of in vitro development of functional islets and in vivo use in diabetic animal models [20]. Scientists
have now generated stem cell–derived $\beta$ cells that express cell markers found on mature $\beta$ cells and exhibit calcium influx, membrane depolarization, and insulin exocytosis in response to a glucose challenge. These cells display the same activity once transplanted under the kidney capsule of immunosuppressed mice. These cells secrete human insulin in a glucose-related manner and ameliorate hyperglycemia for diabetic mice [21]. Although still in its infancy, this exciting discovery has brought scientists one step closer to realizing the potential that cell therapy may play in clinical transplantation.

PANCREAS TRANSPLANT RECIPIENT CATEGORIES

Pancreas transplantation candidates are divided into three categories: uremic (need a kidney transplant), posturemic (have a functioning kidney transplant), and nonuremic (do not need a kidney transplant, at least yet). For candidates who are uremic, the options are to receive kidney and pancreas transplantations either simultaneously in the same operation or sequentially in separate operations. Which option to take is usually based on the availability and suitability of living and deceased donors for one or both organs at that particular time.

Accordingly, there are three broad categories of pancreas transplantation procedures: simultaneous pancreas kidney (SPK) transplantation, pancreas after kidney (PAK) transplantation, and pancreas transplantation alone (PTA).

1. SPK transplantations: Most SPK transplantations are performed with both organs from the same deceased donor. Because a large number of patients wait on the UNOS list for a kidney organ, unless priority is given to SPK candidates, waiting times tend to be long (years). To avoid two operations and long waiting times, a simultaneous kidney and segmental pancreas transplantations from a living donor can be done, but historically only a few centers offered this, and this option has largely fallen out of favor as outcomes with deceased donor pancreas transplantations have improved [22,23]. A simultaneous living donor islet–kidney transplantations have been utilized anecdotally with some success [23,24]. If a living kidney donor is available, another option is a simultaneous living donor kidney and
deceased donor pancreas transplantation [25]. However, due to logistical challenges associated with this approach, more commonly if a patient has an available living kidney donor and is thought to benefit from avoiding prolonged wait times and the morbidity and mortality risks associated with increased duration of dialysis, many centers will proceed with living donor kidney transplant and subsequent PAK.

2. PAK transplantation: For diabetic patients who have already received a kidney transplantation from a living or deceased donor, a PAK transplantation can be performed. Most PAK transplantations today are performed from a deceased donor in a patient who previously received a living kidney transplantation. Although a PAK transplantation requires that a uremic diabetic patient undergoes two operations to achieve both a dialysis-free and insulin-independent state, the two transplantations done separately are “smaller” procedures than combined transplantations. The time interval between the living donor kidney transplantation and the deceased donor pancreas transplantation depends on several factors, including recipient recovery from the kidney transplantation and donor availability. Initial popularity of the PAK peaked at 28% of pancreas transplants performed in the United States in 2004 has now declined to around 12% [7]. Under the new kidney allocation system implemented in December 2014, equal prioritization was given to SPK and PAK recipients, obviating the advantage of shorter wait times with PAK versus SPK. Historically, PAK has been associated with inferior pancreas graft survival and higher rates of rejection compared with SPK transplantation, which has the immunologic advantage of a single donor [7, 26]. More recently, some authors have argued for the increasing reconsideration of PAK especially in the era of modern immunosuppression regimens and improved pancreas transplantation outcomes since this could be performed after a patient receives a living donor kidney transplantation [26]. Improved patient and graft survival has been demonstrated after living donor compared with deceased donor kidney transplantation. Moreover, this approach could enable preemptive kidney transplantation, which is also associated with well-established survival benefits as well as decreased complications and costs.

3. PTA: For recipients with adequate kidney function, a solitary pancreas transplantation can be performed from either a living or deceased donor. With improved outcomes following deceased donor pancreas transplantation, living donor solitary pancreas transplantation is done infrequently, but is typically indicated if a candidate has a high panel-reactive antibody and a negative cross-match to a living donor. PTA candidates have problems with glycemic control, hypoglycemic
unawareness, and frequent insulin reactions but as yet fairly normal renal function. A successful PTA not only obviates these problems, but also probably improves the quality of life and may ameliorate secondary diabetic complications, thus increasing the applicability of PTA [27–29].

Although the numbers of pancreas transplantations have declined over the past decade from a high of more than 1,400 annually in 2004 to 2005 to a little over 1,000 in 2013 and 2014, the most common category of pancreas transplantation is still SPK (76%). Approximately, 12% of pancreas transplantations were PAK or PTA each, respectively [7]. Although rare, pancreas transplants can also occur as multiorgan transplants in patients with unique medical problems.
HISTORICAL PERSPECTIVES, EVOLUTION, AND IMPROVEMENTS IN PANCREAS TRANSPLANTS

The first clinical pancreas transplantation was performed at the University of Minnesota in 1966 [30]. The number of transplants remained low during the 1970s, but progressively increased in the 1980s, due to the introduction of cyclosporine. By the end of 2010, more than 36,000 pancreas transplants were reported to the International Pancreas Transplant Registry (IPTR) from more than 1,000 centers worldwide, including more than 24,000 in the United States and more than 12,000 outside the United States [6]. More than 3,000 patients wait for a pancreas transplantation on the basis of OPTN data in June 2015, and more than 1,000 pancreas transplantations are performed annually in the United States [7].

The early history of pancreas transplantation was largely performed at the University of Minnesota and involved various surgical techniques, many of which were developed to manage pancreatic exocrine drainage [22]. The first clinical pancreas transplant was performed by Kelly et al. as a duct-ligated, segmental graft at the University of Minnesota in December 1966 [30,31]. In 1973, Lillehei described a series of 13 pancreas transplants at the University of Minnesota, first via a cutaneous duodenostomy and subsequently where he used enteric drainage (ED) of pancreatic secretions via a Roux-en-Y duodenojejunostomy [31,32]. In the 1970s, Gliedman reported a series of 11 segmental pancreas transplants with a pancreatic duct–ureter anastomosis for exocrine drainage [31–34]. This technique did not develop widespread popularity because of leakage from the pancreatic duct–ureter anastomosis and the cut surface of the pancreas [31].

From the mid-1970s to mid-1980s, segmental pancreas transplantations predominated due to a historical belief that the pancreatic organ was less antigenic than the duodenal stump [31,32]. It was during this time that islet transplantation was viewed with increasing promise and the hope that it would replace pancreas transplantation. With segmental pancreas transplantations, two techniques were popularized to manage pancreatic exocrine secretion, including open intraperitoneal drainage by Bewick in 1976 and the University of Minnesota in 1978 [31,35] and synthetic polymer pancreatic duct injection by Dubernard in 1978 [31,36]. In 1983, Sollinger [37] reported the use of direct bladder drainage (BD) to manage pancreatic exocrine
secretions in a segmental pancreas graft, and the next year he described a series of 10 segmental pancreas transplantations with BD that had very few surgical complications, and so BD became the predominant technique (Fig. 61.1) [31,37]. Additionally, the ease of measuring urinary amylase activity as a marker for rejection episodes contributed to the popularity of this technique over the next decade [22,31,38].

In the mid-1980s to the mid-1990s, although BD had continued popularity, urinary complications including cystitis, urethritis,
hematuria, metabolic acidosis, and dehydration led to enteric conversion of many whole-organ pancreas transplants in a technique first described by Tom in 1987 [31,40]. For SPK, monitoring of urinary amylase was less important as serum creatinine elevation typically preceded urinary amylase decline when rejection episode affected both organs [22]. As such, ED became the more common technique much earlier for SPK. Since 2010, enteric drainage was used in approximately 90% of pancreas transplantations [6].

![FIGURE 61.2 Enteric-drained simultaneous pancreas and kidney transplant from a cadaveric donor with systemic venous drainage.](image_url)

Venous drainage of the pancreas has also evolved over the years. Portal drainage was used with segmental grafts in the 1980s [41–44]. In 1989, Mühlbacher [45] described the first case of whole-organ pancreas transplantation with portal venous drainage and exocrine BD. Until 1990s, systemic venous drainage had been the norm until portal drainage gained increased popularity with ED [46,47] as opposed to BD [45]. Most commonly, drainage of the portal vein was to the recipient superior mesenteric vein (Fig. 61.3). However, by 2010, the popularity of portal drainage was waning, with only portal drainage utilized in 18% of SPK and PAK and 10% of PTA [6].
Before standard techniques were developed to procure liver and pancreas grafts with intact blood supplies, segmental pancreas grafts were commonly used. Currently, whole-organ pancreaticoduodenal grafts predominate, although segmental grafts are still used for living donor pancreas transplantations. The first living donor pancreas transplantation was performed at the University of Minnesota in 1979 [48]. The early series of living donor pancreas transplantations consisted of solitary pancreata because the technical failure and rejection rates for deceased donor pancreata were so high [22,49]. In the 1990s, living donor pancreas transplantations were predominantly performed in combination with a kidney from the same donor (Fig. 61.4) [50–52]. Another approach, as previously mentioned, is to perform a living donor
kidney transplantation simultaneously with a deceased donor pancreas transplantation [25].

Immunosuppressive regimens have made great strides over the years. Most immunosuppressive protocols use antibody induction, followed by maintenance therapy with tacrolimus in combination with mycophenolate mofetil [53]. Typically, patients received T-cell–depleting induction with either antithymocyte globulin or aletuzemab. Despite initial interest in nondepleting agents, utilization for pancreas transplant had declined to less than 10% according to the IPTR registry [6]. In the late 1990s and early 2000s, some centers including Northwestern University pushed for steroid-free regimens for pancreas transplantations [31]. In fact, according to the IPTR, a third of SPK and up to 45% of PTA/PAK transplantations were discharged on a steroid-free maintenance regimen [6,31,53].

In 2012, there were more than 100 pancreas transplant centers and 12 active allogeneic islet cell transplant centers in the United States [54]. Some centers have reported extensive experience, including more than 1,000 SPK transplantations at the University of Wisconsin and more than 1,900 pancreas transplantations of all categories at the University of Minnesota. Since 1980, the IPTR has collected data from all centers in the world [6,55] and remains an excellent resource for outcome analysis.
In addition, the US Transplant Scientific Registry of Transplant Recipients (SRTR) provides detailed scientific analysis of national, regional, state, and center-specific pancreas graft and patient survival [7].
INDICATIONS AND CONTRAINDICATIONS FOR PANCREAS TRANSPLANTS

The indications for a pancreas transplantation have evolved and expanded over the years as the results have improved. The position statement of the American Diabetes Association [3] on indications for a pancreas transplant (Table 61.1) include patients with impending or existing end-stage renal failure, frequent and severe metabolic complications such as hypoglycemia especially hypoglycemic unawareness, incapacitating clinical or emotional problems with insulin therapy, and failure of insulin therapy to prevent acute complications. Pancreas transplantation also benefits patients who have developed secondary complications of diabetes including retinopathy, cardiovascular disease, nephropathy, and neuropathy. The progression of many of these complications is halted and potentially reversed by a functioning pancreas graft.

TABLE 61.1 Summary of American Diabetes Association Recommendations for Indications for Pancreas Transplants

With a functioning pancreas transplant, improvements with sensory,
motor, and autonomic neuropathy and paresthesias have been reported [56–61]. Patients with abnormal cardiorespiratory neurologic reflexes have reduced death rates after a functioning pancreas transplantation [61,62]. There is increased nerve conduction velocity in SPK recipients with functioning pancreas transplantation versus those with failed pancreas grafts [56,63–65]. Uremic patients who undergo SPK transplantation have improved symptoms of gastroparesis than do patients who have a kidney transplantation alone [57,66].

Similarly, a successful pancreas transplantation halts the progression of diabetic changes in the new kidney transplant, and several studies have demonstrated improvement of nephropathy after PTA [56,57,61]. One study showed that long-term normoglycemia due to a functioning pancreas transplant led to reversal of characteristic diabetic glomerular lesions that occurred in nonuremic PTA recipients who had established nephropathy [57,67]. In addition to improvement in glomerular architecture, this group also showed a reversibility of cortical interstitial expansion and reabsorption of atrophic renal tubules 10 years after PTA [57,68]. These changes in renal architecture may explain the reduction in blood pressure, albuminuria, and nephrotic range proteinuria that some PTA recipients demonstrate [57,69,70], but creatinine clearance can still deteriorate.

Several recent reports have shown stabilization or amelioration of diabetic retinopathy with a functioning pancreas transplant [56,57,61]. Ramsey et al. reported reduced deterioration in advanced retinopathy with a functioning pancreas transplant at 3 years [57,71]. Wang et al. reported regression of diabetic retinopathy in 43% of SPK recipients versus 23% of kidney-transplantation-alone recipients, although nearly 50% of both groups showed no benefit but follow-up was short at 1 year [61,72]. Giannarelli et al. examined 33 type 1 patients who received a pancreas transplantation versus 36 type 1 patients who had medical therapy only and noted that stabilization or amelioration of diabetic retinopathy was 91% versus 43%, respectively [56,73].

Several studies have examined the effects of pancreas transplantation on vasculopathy and cardiovascular risk factors. Severe and advanced vascular disease may be unaffected by a functioning pancreas transplant [56,61]. One series documented improvement in conjunctival microcirculation in 12 SPK patients when compared with five kidney-transplant-alone recipients [57,74], and other series reported improvement in carotid artery intima-media thickness (which correlates with decreased cardiovascular events) within 2 years of pancreas
transplantation [57,61,75,76]. SPK transplants have also shown to improve cardiovascular risk factor profiles, left ventricular systolic and diastolic function, and endothelial function and slow progression of coronary atherosclerotic lesions [56,57,61,77–82]. Atherosclerosis regresses in nearly 40% of recipients with a functioning pancreas transplant, and this fact may explain improved quality of life and patient survival benefit after pancreas transplantation [56,61,82]. Fiorina et al. demonstrated normalization of left ventricular diastolic function at 4 years after a functioning pancreas graft [56,61,83], which leads to reduction in cardiovascular events [79]. Rates of myocardial infarction and pulmonary edema were lower in SPK recipients than in kidney-transplant-alone patients, although the kidney-alone patients tended to be quite older and the follow-up period was short [61,84–86]. Echocardiographic findings 2 years after pancreatic transplantation showed improvement in left ventricular shape and function when compared with kidney transplantation alone. Stabilization [61,62] and even improvement [61,87] in cardiac autonomic dysfunction can occur after pancreas transplantation. A pancreas transplantation preferably can be offered early, before the onset of these complications of diabetes, to interested patients who understand the risks of a significant operation and immunosuppression versus the benefit of insulin independence and freedom from diabetic complications.

Potentially, the most subjective outcome after pancreas transplantation, improved quality of life, may be the most important [57]. One study compared the quality of life of diabetic patients who underwent SPK transplants with a kidney transplants alone and noted that SPK recipients reported improved quality of life in regard to chronic symptoms, effects of kidney disease, cognitive function, pain, physical activity, and overall health [88]. Clear evidence regarding improvement in quality of life after PTA recipients is lacking.

Relative and absolute contraindications include those for any other transplantation, such as extremes of age, prohibitive cardiovascular and pulmonary risk, severe hepatic disease, malignancy, active acute and chronic infections, AIDS, severe persistent coagulation disorder, noncompliance, and serious psychosocial problems. Candidates with advanced vascular disease have increased risks of surgical complications, yet those patients who do well after pancreas transplantation greatly benefit from stabilization of their cardiovascular risk.
PRETRANSPLANTATION EVALUATION

The pretransplantation workup should include a detailed medical, surgical, and psychosocial evaluation. Cardiac risk assessment is mandatory because diabetes is a major risk factor for coronary artery disease (CAD). Cardiologists vary on the type of test to screen for CAD in pretransplantation diabetic patients. Coronary angiograms are performed in many candidates, especially those over 45 years of age. Noninvasive tests are not very sensitive for CAD and are poorly predictive for subsequent postoperative events in long-standing diabetic patients. Risks of contrast-induced nephropathy in patients with residual renal function must be balanced against the potential benefits of accurate cardiac risk stratification and potential intervention when evaluating patients for transplant. Revascularization by angioplasty, stenting, or bypass surgery may be needed when possible to address reversible ischemic and unstable cardiac disease. Revascularized transplantation candidates have significantly fewer postoperative cardiac events, as compared with those who received medical therapy alone. The minimum cardiac evaluation for consideration of pancreas transplant candidacy should include an electrocardiogram, chest radiograph, echocardiogram, and cardiac stress test [61].

A detailed physical examination must be done to rule out vascular insufficiency in the lower extremities. If such vascular insufficiency is found, it too may need pretransplant correction with angioplasty, endarterectomy, or revascularization because the transplant operation, often involving an anastomosis to the iliac artery, may further diminish lower extremity blood flow.

Pulmonary function tests are indicated in chronic smokers and patients with a history of chronic pulmonary disease. Postoperative intensive care unit monitoring and perioperative bronchodilator therapy may be indicated in some patients. Some transplant centers require smoking cessation for consideration for listing. Liver function tests should be done to rule out hepatic insufficiency and viral hepatitis. The diagnosis of viral hepatitis (especially hepatitis C) is associated with worse long-term outcome after extrahepatic transplantation. The presence of cirrhosis is a contraindication for pancreas transplant (unless the patient is a candidate for a multiorgan transplant). Autonomic dysfunction in terms of autonomic neuropathy and gastroparesis are frequent complications of long-standing diabetes. In some cases, symptoms of these can be unmasked or more severe during the early postoperative period. Some immunosuppressive medications also may worsen gastrointestinal dysfunction (mycophenolate mofetil can have significant gastrointestinal
side effects). Prokinetic agents may be indicated to treat gastroparesis. A urologic evaluation is especially important for bladder-drained recipients because bladder dysfunction predisposes to graft pancreatitis and for SPK recipients because it may impact long-term kidney graft function.
CADAVERIC DONOR SELECTION

Pancreas donor selection criteria are not standardized and vary from center to center. Absolute contraindications are the obvious ones applied to most solid organs: active hepatitis B, hepatitis C (unless the recipient has hepatitis C), human immunodeficiency virus, most viral encephalitis, non-CNS malignancy, surgical or traumatic damage to the graft, history of diabetes mellitus, pancreatitis, and extremes of age (less than 10 or more than 60 years). Prolonged intensive care unit stay and duration of brain death have been associated with an increased risk of pancreas graft failure [89]. Many studies have shown that donor age is important. Even middle-aged donors (>45 years old) are associated with pancreas graft failure and increased complications [90–92]. Small donors (<28 kg) have been used for pancreas transplantation with good outcomes [93]. Obesity in the deceased donor is a common cause for refusal of solid-organ pancreas donation, and donors with a BMI > 35 kg per m² are virtually never used for solid-organ pancreas transplantation [61]. According to International Pancreas Transplant Registry data, the following variables are associated with an increased risk of pancreas allograft thrombosis: (1) donor age > 40 years; (2) nontraumatic cause of brain death; and (3) pancreas preservation time >24 hours [53,94]. Other reports have suggested that donor BMI > 30 and fatty infiltration of the pancreas gland on visual inspection increase risks of graft thrombosis [95,96]. Older and obese donors (>50 years old and >30 kg per m²) are probably more suitable for islet cell than for solid-organ pancreas transplantation [61]. Elevated donor sodium levels (Na > 160 mg per dL) is considered a relative contraindication by some centers due to concerns for pancreatic edema and risks of graft pancreatitis and thrombosis. It is one of the factors along with donor age, BMI, duration of cardiac arrest and ICU stay, vasopressor use, and elevated serum amylase and lipase levels that make up the preprocurement pancreas allocation suitability score (P-PASS), which had been associated with differences in pancreatic graft survival rates [97]. Elevated amylase and lipase levels are considered contraindications by many centers, but care must be taken in interpreting amylase levels as these are frequently elevated in donors with head injury. More recently, a pancreas donor risk index (PDRI) score developed by Axelrod et al. [98] on the basis of multivariate regression predicts pancreas graft survival after transplantation on the basis of donor age, gender, race, BMI, height, cause of death, donation after cardiac death status, and elevated serum creatinine.
Still, donors after cardiac death are being used increasingly and successfully to expand the donor pool. One survey showed equivalent patient and graft survival at 1, 3, and 5 years in SPK transplant recipients from donors after cardiac death compared with ideal donors after brain death [64]. In general, a pancreas from a so-called marginal donor is associated with good outcome if the pancreas is found to be normal on gross inspection [64,99].

In nearly 3,200 consecutive pancreas donors procured between 2000 and 2005, Vinkers et al. [100] determined the influence of a “preprocurement pancreas suitability” score on the acceptance or refusal of deceased pancreatic organs. The investigators assigned a weight for several preprocurement factors including age, BMI, length of ICU stay, cardiac arrest as cause of death, serum sodium, amylase and lipase levels, and need for vasopressor support to develop a donor score. When the donor score was ≥17, pancreata from these deceased donors were three times more likely to be refused by transplant centers. Donor scoring systems such as this one may provide more objective information about the quality of a deceased pancreatic organ to promote wider pancreas donor acceptance.

Pancreas Preservation

University of Wisconsin solution was first used for pancreas preservation in a preclinical model in 1987 [101]. As with most solid organs, in vivo flush followed by simple storage in cold University of Wisconsin solution is still the gold standard for pancreas preservation. In the original canine model, pancreata were preserved for up to 96 hours [102], but in clinical transplantation, pancreas cold preservation exceeding 24 hours has been associated with increased graft dysfunction. Even for less than 24 hours, it is evident that the longer the cold ischemia time, the greater the technical complication rate. Therefore, every effort should be made to minimize the cold ischemia time to optimize graft function and to minimize complication rates. A general trend toward shorter preservation time has been noted over time with over 50% of pancreas transplants having a preservation time under 12 hours since 2005 [6].

The two-layer method (TLM) using University of Wisconsin solution and perfluorochemical has been used in clinical whole pancreas transplantation but more commonly for islet preservation [103]. This method improves pancreas oxygenation, allowing for longer preservation time while providing a mechanism for repair of ischemic damage due to cold storage [104–106]. Some studies show that TLM improves islet yields, islet viability, islet morphology, rates of successful islet isolations and transplants, and islet yields from marginal donors [105,107–113].
Other studies report that TLM has no effect or is even detrimental for pancreas preservation and show no difference in islet yields, islet viability, or islet transplant outcomes when pancreatic organs were preserved with the TLM versus University of Wisconsin solution \[54,105,108,114\]. More prospective, randomized, controlled trials are needed before the TLM becomes routine procedure.

Three main preservation solutions for pancreas transplantation are available today, including University of Wisconsin solution, Celsior, and histidine–tryptophan–ketoglutarate solution (HTK) \[105,108\]. HTK has been increasingly used in pancreas transplantation, and its advantages include lower viscosity, less potassium, lower cost, and no need for “on-shelf” cold storage, but it requires more solution to flush organs in the multiorgan donor (8 to 12 L of HTK solution vs. 4 to 6 L of Celsior vs. 4 to 6 L of University of Wisconsin solution) \[105\]. In pancreas transplantation, there have been only one retrospective study \[107\] and two prospective randomized studies \[115,116\], which compare University of Wisconsin solution with Celsior, and both solutions give similar results. Several reports have compared HTK with University of Wisconsin solution and most reports have described equal suitability for perfusion and organ preservation in clinical pancreas transplantation \[117–121\]. In an analysis of the UNOS pancreas transplant database from 2004 to 2008, Stewart et al. \[122\] noted that HTK preservation was associated with a 1.5-fold higher odds of early (<30 days) pancreas graft loss when compared with University of Wisconsin solution and was independently associated with increased pancreas graft loss in SPK and PTA recipients, especially when cold ischemia times were ≥12 hours. Further prospective, randomized studies will be necessary to determine which perfusion and preservation solution provides the best short-term and long-term pancreas graft survival.

**Human Leucocyte Antigen (HCA) Matching**

The impact of HLA matching on outcomes varies. HLA matching appears to have minor effect on patient, kidney, or pancreas graft survival after SPK transplantation \[123,124\], although increased acute rejection rates have been reported with poorer matches \[125–127\]. For PAK and PTA transplants the data are mixed, ranging from studies showing little impact \[128\] to registry data showing that higher HLA A and B mismatches are associated with increased immunologic graft loss \[124\]. A few centers offer desensitization to highly sensitized pancreas transplant candidates on the basis of the utilization of Intravenous Immune Globulin (IVIG) administration and plasma exchange \[129\]; however, this is not a routine practice or considered at most transplant centers. In general, pancreas transplantation is performed after confirmation of a
negative cross-match that can now be accurately predicted on the basis of solid-phase assays, which can identify preformed HLA antibodies.

Anesthetic Considerations in Recipient

A patient with brittle diabetes and secondary complications (e.g., CAD, autonomic neuropathy) can pose special problems for the anesthesiologist. Dysautonomic response to drugs or hypoxia can lead to significant morbidity and even death. It is well documented that long-standing diabetes poses a challenge to the anesthesiologist during intubation. Awareness of these risks and use of an experienced anesthesiology team might help decrease the morbidity and mortality. A major operation such as a pancreas transplantation or combined kidney–pancreas transplantation is often prolonged and can be associated with significant blood loss. Prompt replacement with blood or colloid solutions should be instituted to avoid hypoperfusion after significant blood loss because pancreas hypoperfusion can lead to thrombosis. In the intra- and perioperative period, careful blood glucose monitoring is essential and insulin therapy may be necessary to maintain tight control of blood glucose levels. Blood glucose levels may be affected in the immediate postoperative period due to high-dose steroids, and so supplemental insulin therapy may be required to control hyperglycemia even in the setting of a functioning graft. Perioperative β-blockade should be considered for long-standing diabetic patients with a cardiac history.
BACK-TABLE PREPARATION OF THE DONOR PANCREAS

Back-table preparation of the pancreas organ is necessary before implantation, including these steps:

1. Donor splenectomy (taking care to avoid injury to the pancreatic tail)
2. Shortening the donor duodenum without damage to the main or accessory pancreatic duct (especially important with BD to minimize bicarbonate loss)
3. Ligation of the mesocolic and mesenteric stumps on the anterior aspect of the pancreas
4. Excision of excessive lymphatic and ganglionic tissue in the periportal area
5. Reconstruction of the splenic and superior mesenteric arteries with a donor Y graft including the iliac artery bifurcation (to provide for a single-arterial anastomosis in the recipient)
6. Some mobilization of the portal vein
7. Ligation of the bile duct stump
Several techniques have been described for the recipient operation [130]. The techniques vary on the basis of whether a solitary pancreas transplant (PTA, PAK) or a combined transplant (SPK) is done. Most SPK transplants are performed through a midline intra-abdominal approach, although some are performed through bilateral iliac retroperitoneal incisions.

The major surgical considerations for pancreas transplants include the following:

1. Choice of exocrine secretion of the pancreas, ED versus BD: The 2004 IPTR noted that 81% of SPK, 67% of PAK, and 56% of PTA transplants had ED of pancreatic exocrine secretions [53]. Bladder drainage accounted for 10% to 20% of all pancreas transplants reported to the IPTR from 2004 through 2008 [131]. ED is much more physiologic and eliminates the complications of BD (e.g., acidosis, pancreatitis, urinary tract infections, hematuria, urethritis, urinary stricture, urinary disruption). Between 10% and 20% of BD recipients ultimately undergo enteric conversion at 6 to 12 months because of such complications. BD, however, allows for direct measurement of urinary amylase as a marker of exocrine function. A decrease in urinary amylase is sensitive, but not very specific, for acute rejection of the pancreas [53]. Hyperglycemia is a late event in rejection, and a decrease in urinary amylase occurs early in rejection. Thus, rejection episodes may be detected earlier with BD than with ED. In clinical practice, the choice of exocrine drainage varies. Some groups always use ED, some always use BD, and others determine the choice of exocrine drainage on the basis of the individual recipient’s anatomic constraints and the risk of bowel/urologic complications. Patient and graft survival are similar with both techniques [91,132], but BD is associated with higher rates of urinary tract infections, in addition to urologic and metabolic complications [133,134]. ED is likely to predominate as the major technique in the future, as immunologic strategies to eliminate rejection are further refined. ED usually occurs as an anastomosis between the donor duodenal stump and the recipient proximal jejunum, but graft placement behind the right colon can allow for direct duodenostomy [133,135].

2. Choice of venous drainage, portal or systemic: The 2004 IPTR reported that in enteric-drained pancreas transplants, 20% of SPK, 23% of PAK, and 35% of PTA cases had venous drainage to the portal
Portal drainage is more physiologic than systemic drainage. Theoretically, portal drainage preserves the first-pass metabolism of insulin in the liver. Therefore, pancreas recipients with portal venous drainage will have lower systemic insulin levels than recipients with systemic venous drainage. In one study [136] that compared portal with systemic venous drainage in SPK recipients, there were no significant differences in patient, kidney or pancreas allograft survival rates, or early graft loss by pancreatitis or thrombosis. There were no significant differences in early endocrine function, although HbA1C was lower at 6 and 12 months in the portal-drained group. Portal venous drainage is difficult to perform with BD unless there is a venous extension graft [45]. However, portal venous drainage is likely to increase in popularity, given some reports that rejection rates are lower in this category [132, 137]. Recent modifications include a retroperitoneal portal-enteric drainage technique behind the right colon [138].

Choice of graft, whole-organ or segmental: Almost all deceased donor pancreas transplantations performed today are whole-organ grafts. Segmental grafts have little role to play in this group, except when a rare anatomic abnormality is noted such that the head of the pancreas cannot be used. A rare instance of a split deceased donor pancreas organ transplanted into two different recipients has been described [139]. All living donor pancreas transplants use segmental grafts (body and tail), which are still capable of maintaining normoglycemia in the recipient.
POSTOPERATIVE CARE

After an uncomplicated pancreas transplantation, the recipient is transferred to the postanesthesia care unit or the surgical intensive care unit. Centers that have a specialized monitored transplant unit (with central venous and arterial monitoring capabilities) transition the postoperative recipients through the postanesthesia care unit to the transplant unit. Other centers transfer patients directly to the surgical intensive care unit for the first 24 to 48 hours. Care during the first few hours after transplant is similar to care after any major operative procedure. Careful monitoring of vital signs, central venous pressure, oxygen saturation, urine output, and laboratory parameters is crucial. The following factors are unique to pancreas recipients and should be attended to:

1. Blood glucose levels: Any sudden, unexplained increase in blood glucose levels should raise the suspicion of graft thrombosis. An urgent ultrasound must be done to assess blood flow to the graft. Some centers believe that maintenance of tight glucose control (<150 mg per dL) using an IV insulin drip is important to “rest” the pancreas in the early postoperative period.

2. Intravascular volume: Because the pancreas is a “low-flow” organ, intravascular volume must be maintained to provide adequate perfusion to the graft. Central venous pressure monitoring is used to monitor intravascular volume status. In some cases, such as patients with depressed cardiac function, pulmonary artery catheter monitoring may be required during the first 24 to 48 hours. If the hypovolemia is associated with low hemoglobin levels, then packed red cell transfusions should be given; otherwise, crystalloid (and sometimes colloid) replacement should be used to treat hypovolemia.

3. Maintenance IV fluid therapy: The choice of IV fluid therapy can be 5% dextrose in 0.45% normal saline, as long as IV insulin is used to maintain tight blood glucose control, or 0.45% normal saline to maintain acceptable urine output. In SPK recipients, whose IV fluid rate is based on urine output, dextrose should be eliminated if the urine output is high (>500 mL per hour) because hyperglycemia may cause an osmotic diuresis, leading to worsening hypovolemia. Maintenance IV fluid for BD recipients should also include HCO₃ 10 mEq per L to account for the excess HCO₃ loss, or sodium lactate can be used as an alternative.
4. Antibiotic therapy: Broad-spectrum antibiotic therapy and antifungal therapy are instituted in the perioperative period. Antiviral prophylaxis is similar to that for other solid organs and is driven by cytomegalovirus (CMV) status.

5. Anticoagulation: At the University of Texas Health Science Center at San Antonio, all pancreas recipients receive enteric-coated aspirin 325 mg started on the first postoperative day and continued indefinitely. Recipients of solitary pancreas transplants or “high-risk” SPK transplants also receive an intraoperative dose of heparin (3,000 units), followed by a postoperative regimen of low-dose, continuous IV heparin at 500 units per hour for 24 hours. The partial thromboplastin time for heparin is not measured. Our experience is that therapeutic doses of heparin lead to excessive postoperative hemorrhage that requires reduction in heparin dose, and sometimes red cell transfusion or reoperation.

**Immunosuppression**

Immunosuppression is essential to thwart rejection in all allotransplant recipients. Before the advent of cyclosporine in the early 1980s, dual therapy with azathioprine and prednisone was the mainstay of immunosuppression for pancreas transplants. From the early 1980s to the mid-1990s, cyclosporine was introduced for maintenance therapy and resulted in significant improvement in immunologic outcomes. Since the mid-1990s, tacrolimus and mycophenolate mofetil have replaced cyclosporine and azathioprine as the primary maintenance immunosuppressive medications. In a prospective, randomized, multicenter study of tacrolimus versus cyclosporine in SPK recipients, Saudek et al. [140] noted that 3-year patient and kidney graft survival were comparable, but pancreas graft survival was superior in the tacrolimus-treated cohort (89% tacrolimus vs. 74% cyclosporine). In addition, with antibody induction steroids have been successfully withdrawn or even avoided in some cases [141]. However, a 2014 review of several randomized controlled trials involving steroid avoidance or withdrawal concluded that there was insufficient evidence to support the benefits or harm of steroid withdrawal in pancreas transplantation [142]. Specific immunosuppressive regimens vary among different transplant programs.

Antibody induction has become the mainstay protocol for pancreas recipients. The debate continues as to which antibody preparations are
best in pancreas transplant recipients [143]. The administration of depleting agents such as rabbit antithymocyte globulin (rATG) or alemtuzumab has increased over the years, while the use of IL-2 inhibitors has decreased, with the rationale that depleting antibodies provide good immunosuppressive coverage for innovative immunosuppressive strategies including steroid withdrawal or avoidance and minimization of calcineurin inhibitors.

Results

Outcomes after pancreas transplants have consistently improved over the years. The 2012 SRTR report [144] described pancreas transplant graft survival for patients transplanted in 2007. Adult unadjusted graft survival rates at 5 years for SPK, PAK, and PTA recipients were 73%, 65%, and 53%, respectively, at 60 months. The report does highlight the lack of uniformity by transplant centers in their definition of graft failure.

The latest report from the IPTR [131] focused on pancreas transplants in the United States from 2004 to 2008 and included 4,200 SPK, 1,136 PAK, and 491 PTA cases. One-year patient survival rates for all three categories were more than 95%. One-year pancreas graft survival rates were higher for SPK (84.9%) than for PAK (78.6%) and PTA (78.9%) recipients. Graft loss from rejection at 1 year was low in all three categories (2.1% SPK, 5.5% PAK, 6.6% PTA). In the majority of all transplants, ED was used for duct management (80% to 90%), and of the ED transplants, portal venous drainage use declined (15% to 21% of cases). Although overall graft function did not vary with ED or BD, the technical failure rate was higher in ED transplant recipients.

Donor and Recipient Causes of Pancreas Complications

Donor and recipient factors can influence the postoperative course after pancreas transplantation. In a study of 210 SPK transplants between 1995 and 2007, donor-specific risk factors correlating with postoperative pancreas-related complications included donor age, need for vasopressor support, need for preprocurement blood transfusions, and asystolic events >10 minutes [145]. Increasing donor age and BMI were associated with greater need for postoperative interventions. Graft preservation with HTK solution was associated with significantly higher postoperative complications, as was preexisting cardiac disease in the recipient. The choice of immunosuppression had a significant effect on pancreas-related complications, which were greater after induction therapy with rATG versus daclizumab, and maintenance immunosuppression with tacrolimus/rapamycin or cyclosporine/mycophenolate mofetil versus tacrolimus/mycophenolate mofetil. The duration of the pancreas transplant operation and the presence of elevated C reactive protein were
associated with significantly more postoperative complications that required interventions. In another study, donor obesity (BMI > 30 kg per m²) was associated with greater risk of graft thrombosis and deep wound infections \[146\]. Another trial \[94\] noted that technical failure of the pancreas graft occurred more commonly when (1) the donor BMI was >30 kg per m², (2) the cause of donor death was other than trauma, (3) the preservation time was >24 hours, (4) the duct management was ED versus BD, and (5) recipient BMI was >30 kg per m². In another study, multivariate analysis showed that technical failure of a pancreas transplant appeared to be the most significant risk factor for kidney graft loss \[147\]. This evidence underscores that careful donor and recipient selection in addition to improved preservation and surgical techniques play important roles to minimize complications after pancreas transplantation \[148\].

Surgical Complications

Prevention of surgical complications has critical implications not only on pancreas graft and patient survival, but also on financial impact associated with postoperative care. Early diagnosis and management of surgical complications can limit morbidity; delayed diagnosis and treatment of pancreas complications can lead not only to pancreas graft loss but also to kidney graft loss \[148,149\]. Common surgical complications of pancreas transplantation will now be addressed:

1. Hemorrhage: Postoperative hemorrhage is a frequent reason for early re-laparotomy in pancreas transplant recipients. Hemorrhage can occur from the pancreatic parenchyma, from poorly ligated mesenteric or splenic vascular stumps or from the anastomosis in an enteric-drained or bladder-drained pancreas transplant. The incidence of hemorrhage ranges from 6% to 7\% \[91\], and this risk increases with the use of anticoagulation in the immediate postoperative period. Frequent physical examination and monitoring of hemoglobin help to detect early hemorrhage. Heparin may be temporarily suspended to stabilize the patient. Packed cells should be administered if the recipient has symptomatic anemia. If hemorrhage continues, early operative intervention is indicated. If hemorrhage slows down or ceases, heparin should be resumed at a lower rate and judiciously increased as tolerated.
2. **Thrombosis:** Thrombosis after transplant ranges from 5% to 6% [91], and remains the most common cause of early pancreas graft failure. The risk increases after segmental pancreas transplantation because of the small caliber of vessels [51]. Most pancreas transplant thromboses are due to technical causes. Diagnosis is suspected by sudden hyperglycemia and confirmed by sonogram, computed tomography (CT) angiogram, formal angiogram, or MRI, which reveals an absence of arterial or venous flow to the graft. Aggressive anticoagulation will not prevent pancreas transplant thrombosis due to technical reasons. A short portal vein requiring an extension graft or atherosclerotic arteries in the pancreas graft increases the risk for thrombosis. A recipient narrow pelvic inlet with a deeply placed, poorly mobilized iliac vein, atherosclerotic disease of the iliac artery, a technically difficult vascular anastomosis, kinking of the vein by the pancreas graft, significant hematoma formation around the vascular anastomosis, hypovolemia, and a hypercoagulable state are some of the factors that increase the risk for thrombosis. The most common form of hypercoagulable state in the Western population is factor V Leiden mutation. Its incidence ranges from 2% to 5% but may be as high as 50% to 60% in patients with a history (self or family) of vascular thrombosis [150]. Other causes of hypercoagulable state include antithrombin III deficiency, protein C or S deficiency, activated protein C resistance, and anticardiolipin antibodies [151].

The transplant surgeon must have a high incidence of suspicion of these hypercoagulable states and treat them aggressively to prevent pancreas graft thrombosis. If thrombosis is suspected in the early postoperative period, operative exploration of the graft is warranted and findings of a thrombosed graft usually necessitates removal of the pancreas.

3. **Duodenal stump leaks:** The incidence of duodenal stump leaks ranges from 6% to 7% [91]. A leak from the anastomosis of the duodenum stump to the bowel almost always leads to re-laparotomy. Gross peritoneal contamination due to an enteric leak usually necessitates a graft pancreatectomy. The diagnosis is made by elevated pancreatic enzymes in a patient who has clinical signs of acute abdomen. A plain abdominal radiograph may show free air, and an abdominal CT scan may show free air and extravasation of contrast into the free peritoneal cavity. The differential diagnosis is pancreatitis, abdominal infection, or acute severe rejection. A Roux-en-Y anastomosis to the duodenal stump may be a preferred technique if the risk of leak is thought to be increased during the initial pancreas operation. Other novel techniques such as a venting Roux-en-Y pancreatic duodenoejunostomy have been used in selected recipients [152].

Small duodenal stump leaks in bladder-drained recipients are usually
managed nonoperatively with prolonged catheter decompression of the urinary bladder. The diagnosis of duodenal stump leak is made using plain or CT cystography. Large leaks may require operative intervention, including primary repair, enteric conversion, or even transplant pancreatectomy if there is significant compromise of the duodenal stump.

4. Major intra-abdominal infections: The incidence of significant intra-abdominal infections requiring reoperation ranges from 3% to 4% [91]. Performance of the enteric anastomosis with associated contamination predisposes to this higher rate of intra-abdominal infection, where fungal and gram-negative organisms predominate. With the advent of percutaneous procedures to drain intra-abdominal abscesses, the incidence of reoperations is fast decreasing. If the infection is uncontrolled or widespread, then graft pancreatectomy followed by frequent washouts may be necessary.

5. Renal pedicle torsion: Torsion of the kidney has been reported after SPK transplantation [153,154]. The intraperitoneal location of the kidney (allowing for more mobility) predisposes to this complication. Additional risk factors are a long renal pedicle and a marked discrepancy between the length of artery and vein. Prophylactic nephropexy to the anterior or lateral abdominal wall is recommended with intraperitoneal transplantations to avoid this problem. The colon can be mobilized and reapproximated over a kidney transplant in order to prevent torsion.

5. Others: Other surgical complications that may require re-laparotomy include wound dehiscence, incisional hernia, severe pancreatitis (sometimes hemorrhagic or necrotic), pseudocysts, pseudoaneurysms, arteriovenous (AV) fistula in the graft, severe painful rejection, and bowel obstruction [155]. The overall incidence of re-laparotomy for these complications decreased from 32% in the 1980s to 19% in the 1990s, and the mortality rate in recipients requiring re-laparotomy decreased from 9% to 1% over that same period. Improved antibiotic prophylaxis, surgical techniques, immunosuppression, and advances in interventional radiology have all contributed to this decrease [91].

Nonsurgical Complications

1. Pancreatitis: The incidence of posttransplant pancreatitis varies based on the type of exocrine drainage. Bladder-drained recipients with abnormal bladder function are at increased risk of pancreatitis secondary to incomplete bladder emptying and urinary retention causing resistance to flow of pancreatic exocrine secretions. Other
causes of pancreatitis include drugs (corticosteroids, azathioprine, cyclosporine), hypercalcemia, viral infections (CMV or hepatitis C), and reperfusion injury after prolonged ischemia. Pancreatitis is usually manifested by an increase in serum amylase and lipase with or without local signs of inflammation. An abdominal ultrasound or CT scan may identify an enlarged, edematous, hypoechoic graft. The treatment usually consists of catheter decompression of the bladder for a period of 2 to 6 weeks, depending on the severity of pancreatitis. In addition, octreotide therapy may be used to decrease pancreatic secretions. The underlying urologic problem, if any, should be treated. The patient should be placed on NPO status and total parenteral nutrition should be administered if the pancreatitis is severe. If repeated episodes of pancreatitis occur, enteric conversion of a bladder-drained pancreas transplant may be indicated.

2. Rejection: The incidence of acute rejection ranges from 15% to 30% and immunologic graft loss from 2% to 15% for all types of pancreas transplants at 1 year [156]. The diagnosis is usually based on increased serum amylase and lipase levels in all pancreas transplant patients, and decreased urinary amylase levels in bladder-drained recipients. A sustained drop in urinary amylase levels from baseline should prompt a pancreas biopsy to rule out rejection. For enteric-drained recipients, one has to rely on serum amylase and lipase levels only. A rise in serum lipase levels has shown to correlate well with acute rejection in the pancreas transplant. Other signs and symptoms include tenderness over the graft, unexplained fever, and hyperglycemia (which is usually a late finding). Diagnosis of rejection can be suspected by a hypoechoic, enlarged graft by ultrasound or an enlarged, edematous graft by abdominal CT scan. Diagnosis of rejection can be confirmed by a percutaneous pancreas biopsy [157]. In cases for which percutaneous biopsy is not possible due to technical reasons, empiric therapy for rejection may be started. Rarely, open biopsy is indicated, and transcystoscopic biopsy of a bladder-drained pancreas graft, which was used in the past, has been largely abandoned. Finally, in SPK recipients, isolated pancreas transplant rejection portends a worse renal allograft survival than in patients who experience no rejection [158].

3. Others: Other findings include infectious complications such as CMV, extra-abdominal bacterial or fungal infections, posttransplant malignancy such as posttransplant lymphoproliferative disorder, and
other rare complications such as graft-versus-host disease. Many catheter infections are due to gram-positive organisms, with methicillin-resistant coagulase-negative isolates being quite common [159]. The diagnosis and management of these complications is similar to those of other solid-organ transplantations.

Radiologic Studies

1. Ultrasonography: This is the most frequent study used in pancreas recipients. Noninvasive, portable, and relatively inexpensive, it provides prompt information regarding blood flow to the pancreas, the presence of arterial or venous stenosis or occlusion, thrombosis, pseudoaneurysms, AV fistulae, resistance to blood flow within the pancreas (suggestive of either rejection or pancreatitis), and peripancreatic fluid collections.

2. CT scan: A CT scan provides more detail of pancreatic and surrounding anatomy. Use of oral, IV, and bladder contrast (in bladder-drained recipients) is recommended. Thus, a CT cystogram can be combined with an abdominal CT scan. A CT scan is frequently used as a guide in pancreatic biopsies or in placement of percutaneous drains for intra-abdominal infection.

3. Fluoroscopy: A contrast cystogram can be performed under fluoroscopy and can be used instead of, or in addition to, a CT cystogram to look for a bladder leak. The combination of the tests increases the sensitivity for detecting bladder leaks.

4. Magnetic resonance angiogram (MRA): An MRA is done if vascular abnormalities are suspected on the ultrasound. MRA provides accurate information about pancreatic vascular patency, but it is inferior to standard angiography in providing fine vascular detail.

5. Angiography: This is the gold standard test for evaluating arterial anatomy in and around the pancreas. However, it is rarely employed, except in cases in which angiographic intervention (such as angioplasty, stenting of a stenotic segment, or coiling of an AV fistula or pseudoaneurysm) is planned. Contrast nephropathy is feared in a solitary pancreas recipient with renal dysfunction, and reasonable alternatives (such as ultrasound) are available.
FUTURE DIRECTIONS

For type 1 diabetic patients with kidney dysfunction, an SPK or PAK transplant is the standard of care. A PTA, however, is less common because the long-term risks of diabetes are weighed against the long-term risks of immunosuppression. A successful pancreas transplantation can improve existing neuropathy and nephropathy in diabetic recipients, and the survival after a solitary pancreas transplant is better than remaining on the waiting list [160]. As the risks of immunosuppression decrease with novel methods of tolerance and immunomodulation, the balance will tilt in favor of an early transplantation. The limiting factor will then be the organ shortage, which could be alleviated if xenotransplantation is able to overcome its current barrier of hyperacute rejection.

The application of islet transplantation is rapidly growing. Recent successes suggest that islet transplants can provide all the benefits of pancreas transplants without the risks of major operation. Improvements in islet isolation, islet viability, islet functionality, islet implantation, and immunotherapy will improve islet outcomes so that only one donor will be necessary to achieve insulin independence [161]. Xenotransplantation of islets may be more readily achievable using encapsulation than with other organs. Prolonged diabetes reversal after intraportal xenotransplant in primates has been documented [162] and may pave the way for human xenotransplant trials. Also, stem cells from numerous sources (e.g., bone marrow, adipose, or cord blood) may be manipulated to differentiate into islets in order to provide a rich supply for transplantation, and islet transplants can be combined with immunomodulation and tolerogenic strategies to minimize or eliminate immunosuppression [161]. This combination would provide for minimally invasive islet cell transplantations for all type 1 diabetic patients without the need for long-term immunosuppression. The only scenario that would be better would be the thwarting of autoimmunity before the onset of isletitis, thereby preventing type 1 diabetes mellitus in the first place.

INTRODUCTION

The first experimental intestinal transplant was performed by Alexis Carrel in 1901, when he implanted a segment of bowel into the neck of a dog. The first human intestinal transplants occurred in the 1960s, but these transplants were suspended at that time because of dismal graft and patient survival owing to the lack of effective immunosuppressive protocols. The widespread introduction of calcineurin inhibitors (cyclosporine in the 1980s and tacrolimus in the 1990s) renewed interest in intestinal transplantation as a viable surgical option for patients with short bowel syndrome (SBS) who otherwise required chronic total parenteral nutrition (TPN). Newer immunosuppressive regimens, advances in organ preservation, better donor and recipient selection, refinement in surgical techniques, earlier detection and treatment of infections, and improved postoperative critical care management have all played significant roles in the success of intestinal transplantation since the mid-1990s. The advances in this field are presented in Table 62.1. Although intestinal transplantation remains the least frequent of all transplant types, 1-year graft survival rates have significantly improved and now approach those of other nonrenal transplants. As graft losses owing to technical reasons have diminished, immunologic and infectious issues remain primary challenges facing the field today. As the largest lymphoid organ in the human body and a host for potential infectious pathogens, the small bowel continues to be a difficult solid organ to successfully transplant [1–10].

Pretransplant Evaluation

Intestinal failure is defined as the inability of the intestine to maintain nutrition or fluid and electrolyte balance without long-term TPN [2,4,6–8]. The causes of intestinal failure can be divided into two broad groups: (a) SBS (insufficient bowel length) and (b) functional disorders (impaired intestinal motility or absorption with an otherwise sufficient intestinal length and surface area). Currently, an intestinal transplant is indicated for patients suffering from irreversible SBS who present with life-threatening complications secondary to TPN or underlying medical disease [6]. The Centers for Medicare and Medicaid Services have approved coverage for intestinal transplants in patients with SBS who require TPN with these complications: (a) thrombosis of major venous access sites, (b) frequent central line infections and sepsis requiring hospitalization (more than two episodes per year), (c) impending or overt liver failure related to TPN, and (d) severe and frequent episodes of electrolyte imbalance and/or dehydration despite intravenous fluid supplementation and TPN [3,8,11]. Many feel that patients who are stable on TPN without such complications are usually not intestinal transplant candidates, because their estimated annual survival rate could be higher with TPN support than transplantation. Others have suggested that patients with ultrashort bowel remnants, complete portomesenteric thrombosis, slow growing tumors involving the mesenteric root, pseudo-obstruction, and frozen abdomen have indications for intestinal transplantation [4,8].

The most common cause of SBS requiring intestinal transplantation is extensive surgical resection of the small intestine. Uncommon indications for intestinal transplantation for patients with intestinal failure but without SBS are (a) severe gastrointestinal myopathy or neuropathy (hollow visceral myopathy, total intestinal aganglionosis, and pseudo-obstruction syndrome), (b) gut malabsorption syndromes (microvillous inclusion disease, radiation enteritis, and selective autoimmune enteropathy), (c) neoplastic syndromes involving the root of the mesentery (neuroendocrine and desmoid tumors, often associated with familial adenomatous polyposis or Gardner syndrome), and (d) diffuse portomesenteric thrombosis with high risk of gastrointestinal hemorrhage [2,4,7–9].

The causes of intestinal failure and intestinal transplantation differ for adult versus pediatric populations. Gastroschisis, necrotizing enterocolitis, malrotation with mid-gut volvulus, and atresias are the most common causes in pediatric patients; mesenteric arterial thrombosis/embolism, trauma, Crohn disease, and adhesions are the most frequent causes in adult patients [10]. Most patients (53%) who wait for an intestinal transplantation have an underlying diagnosis of SBS [9].
The development of SBS depends not only on the resected length of bowel but also on the location of the resection and on the retention (or not) of the ileocecal valve and/or the colon. As a rough guideline, most patients can tolerate up to 50% resection of their intestine with subsequent adaptation, without the need for long-term TPN. Loss of greater than 70% of intestine (considered ultra-short gut syndrome), however, usually necessitates some type of parenteral nutritional support. The development of TPN-induced liver failure is much more fulminant in children than adults. For these reasons, pediatric patients with SBS should be referred early for isolated intestinal transplantation before the development of irreversible TPN-induced liver injury [2, 5, 7, 12].

The pretransplantation evaluation is similar to that of other types of solid organ transplantation. The typical laboratory evaluation includes ABO type, HLA type, panel reactive antibody, complete blood count, comprehensive basic metabolic profile, and coagulation profile. Serology studies should be performed for HIV, hepatitis B and C, cytomegalovirus (CMV), and Epstein–Barr virus (EBV). A clear picture of the anatomy of the patient’s gastrointestinal tract is essential [2]. An upper gastrointestinal tract contrast series and abdominal and pelvic computed tomography scan are always necessary in order to plan gastrointestinal tract reconstruction during the transplantation. It is important to estimate actual bowel length and function (transit time with upper gastrointestinal series). Hepatic function should be evaluated carefully, and a transjugular or percutaneous liver biopsy is often required. If there is evidence of significant liver dysfunction, a combined liver-intestinal or multivisceral transplant may be indicated [5, 12]. Duplex sonography of the liver and intra-abdominal vascular system can be useful. Patients with thrombotic disorders need specific hematologic tests to define hypercoagulable states (such as protein C and S deficiency, prothrombin G20210 A and factor V Leiden mutation, and hyperhomocysteinemia) [2]. Conventional abdominal visceral angiography and a comprehensive evaluation of the upper and lower central venous system are mandatory in high-risk patients and those with thrombotic disorders. Absolute contraindications, such as advanced malignancy, severe systemic disease, active infection, and marked cardiopulmonary insufficiency, must be ruled out [2, 6].

Surgical Procedure

Unfortunately, the nomenclature to describe the technical aspects of intestinal transplantation has not been consistent in the literature, particularly when other organs are transplanted with the intestinal graft [8]. Transplant experts convened at the 2007 International Small Bowel Transplant Symposium and attempted to standardize this nomenclature
into two broad categories: with or without simultaneous a liver transplantation. Modifications to these operations then reflect that the transplantation occurs with or without excision of the native foregut. Mazariegos et al. argues that failure to apply standard nomenclature hampers the ability to compare contributions that unique surgical techniques may play in critical data analysis and graft/patient survival [8,13]. The indication for transplantation and the choice of organs to include in the composite graft are defined by the recipient’s baseline disease, vascular and gastrointestinal anatomy, associated diseases (such as liver failure, diabetes, exocrine pancreatic insufficiency, or renal failure), and functional quality of the other abdominal organs.

The three most common types of intestinal transplants include (a) isolated intestinal transplants, (b) combined liver–intestine transplants, and (c) multivisceral or modified multivisceral transplants [1–8]. The most common intestinal transplantation is the isolated intestinal graft which includes the entire deceased donor jejunum and ileum, and is used for patients with intestinal failure that is limited to the small bowel. The arterial anastomosis is based on the recipient superior mesenteric artery or using a jump graft from the infrarenal aorta. Venous outflow is usually achieved with the anastomosis of the superior mesenteric vein to the native superior mesenteric vein or splenic vein; however, in some cases, systemic venous drainage to the inferior vena cava is required which can cause metabolic abnormalities. Gastrointestinal continuity occurs with a primary anastomosis between the recipient and donor proximal jejunum and the creation of a distal Bishop-Koop or loop ileostomy with or without anastomosis to the recipient colon. In living donation or in a case of severe donor-to-recipient size mismatch (deceased donor adult to pediatric recipient), a 200-cm length of distal small bowel is used; inflow to the graft is via the ileocolic artery, and outflow is via the ileocolic vein. In patients with combined pancreatic dysfunction (e.g., cystic fibrosis, type I diabetes, or chronic pancreatitis), the inclusion of the pancreas should be considered with intestinal transplantation.

The second most common technique combines the liver and pancreas organs with the intestinal transplantation [1–8]. The liver, pancreas, and intestine (including the duodenum) are procured en bloc from the donor and are transplanted on bloc in the recipient. In the en bloc donor allograft, the arterial inflow is based on an aortic conduit that includes the celiac trunk and the superior mesenteric artery, and the venous outflow that is based on the hepatic veins or the inferior vena cava. The recipient operation includes an arterial anastomosis that occurs between
the donor aortic conduit and the recipient suprarenal or infrarenal aorta; a vena caval anastomosis that occurs via standard caval replacement or by the piggyback technique. Gastrointestinal continuity is reestablished with a primary anastomosis between the proximal donor and recipient jejunum or duodenum and distal creation of the Bishop-Koop or loop ileostomy with or without connection to the recipient colon. The clear advantage of the en bloc liver, pancreas, and intestinal transplant is avoidance of hilar dissection and fewer donor-related arterial or biliary complications that can occur especially in pediatric patients. In this configuration, the common bile duct remains intact in the hepatoduodenal ligament along with the second portion of the duodenum and whole pancreas, which obviates biliary reconstruction of the recipient [8].

A technical variation of liver-intestinal transplantation is that the liver and intestine can be transplanted individually without the pancreas [3,6–8]. The advantage of this technique is that one could excise the intestine if severe complications occur (e.g., hyperacute or acute rejection) and leave the liver intact. The disadvantage of this technique is that it requires multiple vascular anastomoses and biliary reconstruction with their potential complications. In the liver-intestinal transplant, the stomach, duodenum, pancreas, and spleen are left intact, and a portocaval shunt is required for venous outflow of these native organs [2,3,6].

The third type of transplantation, including the intestine, is the multivisceral transplant. In the multivisceral transplant, additional gastrointestinal organs can be transplanted in continuity with the intestine, including the donor stomach, duodenum, and colon with or without the liver and/or pancreas. The common indications for multivisceral transplantation include, but are not limited to, hollow visceral myopathy or neuropathy, pseudo-obstruction syndrome, extensive gastrointestinal polyposis, neuroendocrine tumors, and symptomatic total splanchnic vascular thrombosis. The operation involves complete splanchnic evisceration and en bloc transplantation of the stomach, duodenum, pancreas, liver, and small bowel, and, on occasion, the right and transverse colon (full multivisceral transplant). If the stomach is involved in the upper abdominal evisceration, gastrointestinal continuity is achieved by connecting the donor stomach to the recipient distal esophagus or small gastric remnant. In patients with preserved liver function, the native liver is left intact (modified multivisceral transplant). For patients with chronic or impending renal failure, a renal graft (usually right kidney) can also be included in the multivisceral transplant.

As mentioned earlier, the nomenclature for multivisceral transplantation can be somewhat confusing in the literature. Some authors restrict the term “multivisceral” to transplants that contain the
stomach, whereas others use the term for any combination of abdominal organs [8]. Other reports use the term “multivisceral” only when native organs are simultaneously excised during the transplantation process. Early series suggested that inclusion of the colon increases the risk of infectious complications, but more recent reports describe that inclusion of the colon is not only safe, but may lead to better absorption of water from stool, resulting in fewer episodes of dehydration from diarrhea and hospital readmission [8]. The inclusion of the stomach is also a controversial topic, in that some centers universally apply this technique and other centers rarely or never do. Evidence regarding the benefits and risks of including the stomach in the multivisceral transplant is limited [8].

The recipient operation can be a challenging procedure because of the presence of abdominal adhesions from multiple previous operations, stomas, gastrojejunostomies, reduced abdominal space, and, in some cases, considerable portal hypertension (if the patient requires a liver transplant). The loss of abdominal domain is a unique problem with intestinal transplants unless the patient has significant ascites from liver failure or hollow visceral myopathy or neuropathy (e.g., pseudo-obstruction syndrome). Loss of domain has been addressed with several innovative techniques, including transplantation of the abdominal wall, placement of tissue expanders, and staged closure of the abdominal wall with musculocutaneous free flaps [8].

Gastrojejunostomy tubes are almost always placed intraoperatively, permitting gastric decompression and enteral nutrition in the early postoperative period [2,6,14]. A Bishop-Koop or loop ileostomy is used to decompress the terminal ileum and to facilitate enteroscopy/biopsy, which is the only reliable method to monitor the allograft for acute rejection. The ileostomy is usually taken down within 1 year after transplantation if there is little need to continue monitoring the graft for rejection. Of note, a prophylactic (donor or native) appendectomy and (donor or native) cholecystectomy are performed in all cases to avoid associated postoperative complications. Finally, for a multivisceral transplantation, a donor pyloroplasty is always performed to enable gastric emptying.

Several factors should be considered in appropriate matching of the donor and the recipient for an intestine transplantation. Usually, ABO-identical grafts are used; ABO nonidentical but compatible grafts are usually avoided because of a higher risk of graft-versus-host disease. Donors are typically young, hemodynamically stable, brain-dead but heartbeating donors. Donors should usually be of similar or smaller size than the recipients, because the latter usually have contracted peritoneal cavities, so that a smaller graft may be more appropriate because of space constraints. Selective bacterial and fungal decontamination of the gut
(enteral amphotericin B, polymyxin B, and gentamicin) through a nasogastric tube should be attempted for all donors. CMV enteritis can be a devastating problem in intestinal transplant recipients, so that, if possible, CMV seronegative recipients should receive CMV seronegative intestinal grafts. If possible, similar viral matching should be performed for EBV, when possible, because of the risk for posttransplant lymphoproliferative disorder (PTLD) [2].

Postoperative Care

The early posttransplantation care, in many ways, is similar to that of other solid organ transplantation recipients. Postoperative care for intestinal transplant recipients can be difficult and complicated, especially for those recipients who present with deterioration/malnutrition and organ system failures, when sequelae can persist postoperatively even with improving allograft function. Postoperative management often requires an aggressive, interprofessional approach by medical, nursing, and ancillary health care providers [2]. Initial care is usually in a critical care setting, so that vital signs, urine output, fluid and electrolytes, and blood product replacement can be carefully monitored. Serial hemoglobin measurements are performed to monitor for evidence of hemorrhage. Serum pH and lactate should also be followed for evidence of intestinal ischemia or injury. In patients who received liver-intestinal or multivisceral allografts, pancreatic enzymes and liver function tests should be assessed daily to track organ functional status. Selective bacterial and fungal gut decontamination through a nasogastric tube or gastrojejunostomy tube postoperatively should be performed until enteral nutrition is tolerated. Broad-spectrum antibiotics against bacteria and fungi are routinely administered given the high risk for infectious complications. Routine prophylaxis should also be administered against CMV, EBV, and Pneumocystis jiroveci infection [2]. P. jiroveci prophylaxis for patients with allergies/intolerance to sulfa medication can be accomplished by monthly inhaled pentamidine.

Continuous intravenous fluids are administered in the postoperative period until the patient is stable from a surgical viewpoint [2]. Postoperative nutritional support initially occurs by resumption of standard TPN solutions. When the gastrointestinal function begins to recover and upper gastrointestinal contrast studies confirm the integrity of gastrointestinal anastomoses, enteral nutrition is initiated via the
gastrojejunostomy tube. Most tube feedings are polymeric formulas containing whole complex components instead of a predigested product which can be switched to fiber-containing formulas if significant diarrhea develops [14]. This switch from parenteral to enteral nutrition is gradual and usually occurs in the first 2 weeks after transplantation. Tube feeding is slowly decreased and removed, whereas oral intake is increased proportionately to an unrestricted diet, except in patients with a chylous leak who should receive a low-fat diet. All patients receive antiulcer prophylaxis with proton pump inhibitors, and some patients require antidiarrheal (opiates, loperamide, or soluble fiber supplements) or prokinetic agents (metoclopramide or erythromycin) to modulate stool or stoma output, once rejection or enteritis is ruled out [2].

Most patients can be weaned from TPN and remain TPN free after intestinal transplantation [8]. Matarese reported that enteral nutrition began through a jejunostomy tube at a mean 10.3 days after transplant, that TPN was discontinued at a mean 30.8 days after transplantation and that most patients achieved a regular oral diet at a mean 57 days after transplant [14]. In the early postoperative period, some patients who receive a multivisceral transplantation do not take oral nutrition that is sufficient to meet their nutritional needs. This eating disorder, usually seen in the pediatric population, is caused by many etiologies, including (a) some patients never had the opportunity to eat food before the transplant and never learned the mechanics of food consumption, (b) some patients have associated the act of food consumption with disagreeable and distasteful sentiments with accompanying nausea, vomiting, diarrhea, and abdominal distension and pain, and (c) some patients develop a hyperactive gag reflex evoked by food consumption [2]. Many of these are learned behaviors, and these patients require cognitive redirection of their perceptions around food consumption. They need regular emotional support and nutritional guidance after intestinal transplantation. They often require very slow introduction of new foods. The use of small frequent meals, prokinetic and antidiarrheal agents, and appetite stimulants aid in the transition to regular diets for patients with early satiety, diarrhea, or anorexia [14].

Some intestinal recipients exhibit renal dysfunction in the postoperative period as a result of inadequate intraoperative resuscitation, dehydration from diarrhea/increased stomal output, and high-dose tacrolimus immunotherapy. All patients in the immediate postoperative period have a urinary catheter to monitor the adequacy of resuscitation and appropriate urine output. The increased use of induction immunotherapy for intestinal transplants has led to delayed introduction/decreased target levels for tacrolimus which may translate to more rapid recovery of renal function in the immediate postoperative period and preserved long-term renal function [8].
Immunosuppression should be initiated in the immediate postoperative period [2]. A number of different immunosuppressive protocols have been described. The OPTN/SRTR 2013 Annual Data Report noted that 54% of intestinal recipients received T-cell depleting agents and 11% received interleukin-2 receptor antagonists for induction therapy; yet, 38% received no induction therapy. In this report, the most common initial maintenance immunosuppressive medications were tacrolimus (95%), steroids (73%), mycophenolate (35%), and mTOR inhibitors (15%). Seventy percent of recipients were still maintained on oral steroids 1 year after the intestinal transplantation. Target trough levels for tacrolimus in the whole blood were typically 12 to 15 ng per mL for the first postoperative month, followed by levels of 8 to 12 ng per mL for the next 3 months.

Regardless of the immunosuppressive regimen, intestinal transplants clearly have a high risk of rejection. The ORPN/SRTR 2013 Annual Data Report indicates that the incidence of a first rejection episode increases over time. In adult recipients of isolated intestinal transplants, 45% experience an episode of acute rejection within the first year and 53% within the second year. Although the use of induction agents and tacrolimus-based maintenance therapy have markedly reduced episodes of acute rejection for intestinal transplantation patients, the consequences of steroid resistant rejection carry a 50% mortality in adult intestinal transplant recipients mainly as a result of sepsis [8,15].

Although traditional treatment for acute rejection aims to control the T-cell–mediated response in the intestinal graft with steroid bolus or antilymphocyte therapy, recent attention has been paid to the role of antibody-mediated mechanisms in intestinal graft rejection [8]. Antibody-mediated rejection continues to be a problem in intestinal transplants, because it is relatively resistant to corticosteroid therapy, but donor-specific antibodies in particular are becoming recognized as causes of chronic rejection and late graft loss [16]. This recognition has followed the widespread introduction and implementation of new immunologic technologies, namely, single antigen fluorescent bead assays to detect donor-specific antibodies. The presence of preformed donor-specific antibody and/or increased panel reactive antibody correlates with rejection and graft loss [8,16]. Both preformed and de novo donor-specific antibodies have been associated with antibody-mediated rejection and decreased graft survival; patients with donor-specific antibodies before and after the intestinal transplantation appear to have the lowest long-term graft survival because of not only to episodes of acute rejection but also to chronic allograft enteropathy. Important features of chronic allograft enteropathy are mucosal atrophy and ulceration, mesenteric lymphoid depletion, and mesenteric fibrosis and sclerosis, caused by mesenteric vasculopathy that is highly dependent on
donor-specific antibodies [16]. The presence of CD4 and direct evidence of other antibody and complement activity in mesenteric vasculopathy associated with chronic allograft enteropathy may be lacking in the literature, largely because they are best seen on full-thickness intestinal biopsies and not the typical mucosal biopsies. Finally, complement activation appears to play a significant role in the development of late dysfunction and chronic allograft enteropathy [16]. Donor-specific antibodies can bind to the C1q component of complement, activating the full complement cascade. Of note, inclusion of the liver along with the intestine seems to protect the recipient from intestinal rejection, either by inducing a tolerogenic state in the antigen-presenting cells in the liver or providing a reservoir to sequester sensitized T-cells and/or antibodies against the intestine. Larger studies are necessary to define the use of immunosuppressive medications/therapies to target these various mediators of rejection: preformed donor-specific antibodies (plasmapheresis and immunoglobulin), cytokines (infliximab), B cells (rituximab), plasma cells (bortezomab), and early activation of the complement cascade (eclizumab) [8,16].

In a patient with intestinal dysfunction, it is very important to differentiate enteritis (mostly caused by Clostridium difficile, adenovirus, CMV, and calicivirus) from rejection, because both conditions may be characterized by low-grade fever, abdominal distension and pain, and diarrhea (or increased stoma output). The stoma if present should be carefully examined for color, texture, and friability; in the face of rejection, the stoma may appear edematous, erythematous, pale, congested, dusky, or friable. Endoscopy should be performed for inspection of the mucosa and for purposes of biopsy of the most suspicious areas. Endoscopy with biopsy is the primary method to diagnose allograft rejection. Careful evaluation of an intestinal biopsy by an experienced pathologist is always necessary [2].

Because surveillance and diagnostic endoscopy and biopsy are costly and invasive procedures, there is increased interest to identify potential biomarkers of intestinal rejection [8]. Recent studies have shown that several molecules, namely, calprotectin and citrulline, measured in the stool/ileostomy effluent and blood, respectively, are reliable markers of moderate and severe intestinal rejection. Calprotectin is an S100 protein released by infiltrating neutrophils and macrophages into the gut lumen; increased calprotectin levels have been noted prior to the onset of histologic changes of acute rejection, and normal levels are consistently seen with normal intestine graft biopsies [8,17]. Citrulline is an amino
acid found almost exclusively in enterocytes, so decreased levels in the blood reflect decreased functional mass of enterocytes [17]. Hibi et al. noted that citrulline levels were inversely proportional to the severity of acute cellular rejection [18]. Negative predictive values for any type of acute cellular rejection (cutoff was 20 µmol per L) and moderate/severe acute cellular rejection (cutoff, 10 µmol per L) were 95% and 99%, respectively. Subgroup analysis showed a strong correlation of citrullene levels (obtained up to 1 week prior to biopsy) with the severity of acute rejection on intestinal biopsy; as the citrulline level decreased, the grade of rejection on biopsy worsened. Other potential markers of intestinal graft dysfunction could include adipsin, C-reactive protein (an inflammatory marker used clinically in Crohn disease), and lathosterol (fecal marker of bile malabsorption when intestinal mucosa is dysfunctional) [17]. Larger studies are needed on all of these potential biomarkers in order to be used widely in clinical practice. Girlanda et al. used liquid chromatography to examine the metabolomic profile of ileostomy effluent of patients who had intestinal graft rejection versus no rejection [19]. These investigators noted the highest-fold change in the proinflammatory mediator leukotriene E4 in patients with rejection, and high-fold changes in taurocholate and water-soluble vitamins B₂, B₅, and B₆ in patients with rejection. Metabolomic analysis could be a promising tool to characterize the pathophysiologic mechanisms of intestinal graft rejection and to identify some potential early noninvasive biomarkers of graft dysfunction.

Short-term results have improved dramatically, mainly because of improvements of surgical techniques and immunosuppression regimens. Nonetheless, intestinal transplants are still associated with fairly high surgical complication rates. Potential complications include enteric leaks with generalized peritonitis or localized intra-abdominal abscesses, biliary leakage and stricture (if a liver transplant occurs), graft vascular thrombosis/stenosis, and life-threatening intraoperative and postoperative hemorrhage [2].

Infectious complications are, unfortunately, very common in intestinal transplantation recipients and are a frequent cause of morbidity/mortality and hospital readmissions [2,8]. There are several factors that contribute to this issue. The intestinal graft itself is a significant source of bacteria, and any process which compromises containment of these bacteria (intraoperative spillage of gastrointestinal contents or postoperative anastomotic leak) can lead to a localized abscess or systemic infection. Because of the higher risk of rejection, intestinal transplantation recipients generally receive higher levels of immunosuppression compared with other organ recipients and they are at greater risk for severe infections, including transplant-associated infections (CMV or EBV) and community-acquired pathogens.
(respiratory syncytial virus or influenza). The presence of uncorrected surgical/technical/mechanical problems (e.g., biliary leak or stricture for liver transplantation, gastrointestinal anastomotic leak, vesicoureteral reflux for kidney transplant recipients) may predispose intestinal recipients to recurrent infections [20]. If rejection causes disruption of the intestinal mucosal barrier, bacteria and fungi can translocate across the graft directly into the peritoneal cavity, leading to spontaneous bacterial peritonitis. Bacteria can also spread directly into the portal circulation, and subsequently disseminate to distant sites. Patients with indwelling catheters (central catheters for TPN or gastrojejunostomy tubes for enteral nutrition) are at increased risk for infectious complications until the catheter is no longer necessary and is removed [20]. Finally, immunosuppression attenuates the native immune response to vaccines in the postoperative period; when a higher level of immunosuppression is required for an intestinal transplantation recipient (e.g., rejection treatment), it puts pediatric patients at significantly higher risk for vaccine-associated diseases. Live viral vaccines are contraindicated for intestinal recipients in the postoperative period, placing pediatric patients at risk for varicella in addition to measles, mumps, and rubella if they have exposure to these viruses [20].

Bacterial infections are extremely common in the immediate postoperative period after an intestinal transplant. In a study of 40 adult intestinal recipients, Premegia et al. reported a 30-day postoperative infection rate of 58% with a mean time to first infection of 11 days [21]. In this study, 23 patients developed 36 bacterial infections; of patients with infections, 57% developed one infection, 30% developed two infections, and 13% developed three infections. The most common site of infection was the abdomen, followed by infections in the blood, urine, lung, and surgical site. Of the microbial isolates, 49% were gram-negative bacteria, 39% were gram-positive bacteria, and 11% were fungi. The most common bacterial isolates included Pseudomonas (19%), Enterococcus (15%), and Escherichia coli (13%). Of note, 47% of these infections were caused by multidrug-resistant pathogens. Postoperative bacterial infections remain important complications in intestinal transplantation recipients, and multidrug-resistant pathogens have emerged as a significant clinical challenge.

Fungal infections remain important infectious complications after intestinal transplantation, but data, particularly in pediatric recipients, are lacking in the literature. In a series of 98 pediatric intestinal recipients, Florescu et al. reported that 25 patients developed 59 episodes of Candida infections and four episodes of invasive Aspergillus infections [22]. Of the Candida species, 37% were Candida albicans, and 63% were non-albicans. Of all fungal infections, 66% were in the blood, 29% were in the intra-abdominal space, 3% were in the urinary tract, and 2% were
in the pleural space. Of the *Candida* intra-abdominal infections, 41% developed in the first postoperative month, whereas 80% of fungemia developed after more than 6 months. Median time from intestinal transplant to fungal infection was 9 days for intra-abdominal infections versus 163 days for fungemia. Fungal infections occurred in approximately 25% of pediatric intestinal recipients, and *C. albicans* was the most common species. Intra-abdominal fungal infections occurred much earlier than fungemia after pediatric intestinal transplants.

In addition to bacterial infections, viral infections are also common for intestinal transplant recipients, of which CMV and EBV receive the most attention in the literature [2,8,23]. CMV is the most important viral infection of intestinal recipients. Not only does CMV cause tissue-invasive disease, it is also an independent risk factor for secondary bacterial and fungal infections and PTLD. It can also induce intestinal graft injury and rejection through indirect immunomodulatory causes. The patients who are at highest risk for CMV infection are CMV-negative recipients who receive CMV-positive intestinal organs. CMV-positive recipients are also at risk of CMV infections because of reactivation of latent virus. Antilymphocyte induction therapy further enhances the risk of CMV infections. In patients who receive no prophylaxis, CMV occurs most often within the first 3 months after intestinal transplant, and can present as an asymptomatic infection or as a syndrome, including fever, leukopenia, encephalitis, retinitis, pneumonitis, hepatitis, or enteritis/grant involvement. Antiviral therapy is effective in the prevention and treatment of CMV. For prevention of CMV, patients can receive either universal prophylactic therapy or preemptive therapy. Most experts recommend universal prophylactic for CMV-negative recipients who receive CMV-positive intestinal organs, and universal prophylaxis or preemptive therapy for CMV-positive recipients for 3 to 6 months postoperatively or during intensified immunosuppressive treatments for rejection. CMV-negative recipients who receive CMV-negative intestinal organs are at the lowest risk of CMV infection, and many experts recommend no CMV-specific antiviral prophylaxis [23]. Historic reports noted CMV to occur in 24% of intestinal recipients, but in a recent study of pediatric intestinal transplants, Florescu et al. reported an 11% incidence of CMV viremia and a 7% incidence of CMV disease; in those patients with CMV disease, there was a high rate of CMV disease relapse and an 11-fold increased risk of postoperative mortality [24].

EBV is also an important viral infection, especially in pediatric patients who have received an intestinal transplantation [2,8,23]. Like CMV,
patients with the highest risk for EBV infections are EBV-negative recipients who receive EBV-positive intestinal organs. EBV-positive recipients are at increased risk for reactivation of the latent virus which occurs 2 to 3 months postoperatively. EBV typically causes a syndrome which can include fever, leukopenia, thrombocytopenia, hepatitis, pneumonitis, or PTLD. PTLD can present as a spectrum of diseases ranging from infectious mononucleosis to frank lymphoma that can be nodal or extranodal, localized or disseminated. A positive polymerase chain reaction for EBV in a patient with signs/symptoms of PTLD suggests the diagnosis, but tissue biopsy is mandatory for confirmation. Decreasing the immunosuppression by approximately 50% is the primary treatment which can result in lesion regression. Other treatment options can include surgical resection and radiation therapy for local disease, in addition to rituximab (if CD20 positive) and chemotherapy for disseminated disease. Some centers use antiviral prophylaxis for EBV-negative recipients who received EBV-positive intestinal organs [23].

There is some evidence that intestinal transplantation improves quality of life compared to chronic TPN. In a study of 33 patients on chronic TPN versus 22 patients after intestinal transplantation, Pironi et al. noted that the intestinal recipients had better scores on treatment-specific quality of life questionnaires in the following categories: ability to vacation/travel, fatigue, gastrointestinal symptoms, stoma management/bowel movements, and global health status/quality of life. Subgroup analyses of patients who were employed showed that intestinal transplantation recipients had better scores in the ability to secure and maintain employment and emotional function. These data suggest that a successful intestinal transplant was associated with less uncertainty about employment and, consequently, less anxiety and/or depression [25].

Outcomes

The UNOS Database reported that approximately 2,500 intestinal transplantsations have been performed in the United States over the last 25 years [10]. The OPTN/SRTR 2013 Annual Data Report indicated that only 23 centers performed pediatric intestinal transplants, and only 24 centers performed adult intestinal transplants in the United States [9]. According to this report, the most common cause for intestinal failure was short gut syndrome (53%), caused by a host of etiologies. In this report, approximately 170 new candidates were added to the waitlist for an intestinal transplantation in 2013; of these candidates, 49% waited for a liver-intestinal transplant and 51% waited for an intestinal transplant. Since 2008, candidates listed for an intestinal transplantation outnumbered candidates listed for a liver-intestinal transplantation. In the last decade, the age distribution of listed candidates shifted from a
pediatric to an adult population, but the race or cause of disease distributions did not changed over that period.

According to the 2013 OPTN/SRTR Annual Report, mortality on the waitlist decreased significantly for all age groups over the last decade [9]. Pretransplant mortality was higher for adult candidates than for pediatric candidates, and was higher for candidates who waited for a liver-intestinal transplant than for an intestinal transplant. This decrease in mortality was likely because of a greater proportion of candidates listed for an intestinal transplantation than a liver-intestinal transplantation (higher mortality risk liver failure patients), improved medical therapies for intestinal failure, and improved organ allocation policies. Regarding 3-year outcomes of intestinal candidates, 69% received intestinal transplantation, 8% were removed from the waitlist, 5% died on the list, and 19% continued to wait on the list. Regarding 3-year outcomes of liver-intestinal candidates, 66% received liver-intestinal transplantation, 11% were removed from the waitlist, 11% died on the list, and 12% continued to wait on the list. Among candidates listed in 2012 to 2013, the median time to adult liver-intestinal transplantation, adult intestinal transplantation, and pediatric liver-intestinal transplantation was 11 months, 4 months, and 7 months, respectively. Among pediatric candidates listed in 2008 to 2009, the median wait time to intestinal transplant was 19 months.

In the 2013 OPTN/SRTR Annual Report, the overall number of liver-intestinal transplantations and intestinal transplantations decreased steadily since 2009 [9]. It was noteworthy that in 2013, the overall number of adult intestinal transplantations was more than double the number of pediatric intestinal recipients. Moreover, liver-intestinal transplantation recipients were younger than intestinal transplantation recipients, were more likely to have a diagnosis of necrotizing enterocolitis or congenital short gut syndrome, and were likely to be hospitalized at the time of the transplant. In 2013, 52% recipients received an intestinal graft with another organ, and 19% of liver-intestinal recipients received a previous intestinal transplantation compared to only 2% of intestinal recipients.

According to the 2013 OPTN/SRTR Annual Report, intestinal graft survival has steadily improved over the last decade [9]. Graft failure within the first 3 months occurred in 14% of intestinal transplants and 11% of liver-intestinal transplants. For all intestinal transplantations in 2008, the 1- and 5-year graft survival rates were 73% and 62%, respectively, for pediatric recipients and 76% and 38% for adult recipients. One- and five-year graft survival rates were 79% and 48%, respectively, for all intestinal recipients and 71% and 49% for all liver-intestinal recipients. The number of recipients who were alive with a functional intestinal graft steadily increased over the last decade. The
incidence of acute rejection increased in the postoperative period
approaching 53% at 2 years. For transplantations that occurred from
2001 to 2011, 10% of intestinal recipients and 7% liver-intestinal
recipients developed PTLD with 5 years postoperatively; and the
incidence was highest in EBV-negative intestinal recipients. Regardless of
recipient age, patient survival was better for intestinal recipients than for
liver-intestinal recipients. Pediatric intestinal recipients had the highest
1- and 5-year patient survival rates at 89% and 81%, respectively, whereas
adult liver-intestinal recipients had the lowest 1- and 5-year patient
survival rates at 69% and 46%, respectively.
SUMMARY

Intestinal transplantation is a viable option for patients who suffer irreversible, life-threatening intestinal failure. The causes of intestinal failure vary greatly in the pediatric compared to the adult population. Evaluation of a patient who requires an intestinal transplantation is similar to the evaluation of other solid organ recipients, but a very clear picture of the patient’s gastrointestinal tract and vascular system is essential. It is important to rule out whether the patient also has hepatic, pancreatic, or renal dysfunction that warrants more detailed investigation. There are several surgical options available to patients, including the isolated intestinal transplantation, the liver-intestinal transplantation, and the multivisceral transplantation. These operations can be complex and challenging with potential for significant medical and surgical postoperative complications. A systematic interprofessional approach is mandatory to manage these patients in the preoperative, intraoperative, and postoperative settings. Despite significant improvements in immunosuppressive therapy, acute rejection of the intestinal graft remains a significant complication. Greater attention has been given to the role of donor-specific antibodies and complement in causes of chronic allograft enteropathy and graft loss, and in potential noninvasive biomarkers to diagnose acute allograft rejection. Because intestinal recipients require increased immunosuppression to prevent rejection, they are at increased risk for bacterial, fungal, and viral infections. Multidrug-resistant bacteria, Candida, CMV, and EBV can particularly problematic in the postoperative period. The demographics of the intestinal transplants have changed significantly over the last decade with an increased age of recipient and frequency of isolated intestinal transplantations. With improved graft and patient survival after intestinal transplantation, it does seem counterintuitive that the numbers of intestinal transplantations have decreased over the last few years. With so few US centers performing pediatric or adult intestinal transplants, there could be issues of access to care and financial coverage of medical care/surgical procedures. In conclusion, intestinal transplantation is an attractive alternative option to long-term maintenance therapy with TPN. The future for intestinal transplantation will likely see improvements in surgical techniques and newer medications to treat rejection and infections, which translate into better graft and patient survival. Care of these patients in the critical perioperative period remains a crucial aspect of ensuring a successful outcome.

Immunosuppression in Solid-Organ Transplantation

MARTIN N. WIJKSTROM • SUNDARAM HARIHARAN • ABHINAV HUMAR

Solid-organ transplantation as routine clinical care required breakthroughs in our understanding of immunology and immunosuppressive therapy. Alexis Carrel, in the early 1900s provided the techniques required (vascular anastomosis); experimental transplants soon followed [1], but the first successful clinical transplant was not done until five decades later. During that interval, it gradually became apparent that early rapid destruction of allografts was due to an immune process, which came to be known as rejection.

Organ transplantation is now routine clinical care because results have improved remarkably with the use of more potent, effective, and targeted immunosuppressive agents. Besides the developments in techniques and immunosuppression protocols, progress in tissue typing and cross-matching, progress in organ preservation allowing for transportation of deceased donor organs, effective anti-viral medications, and tests including viral Nucleic acid amplification test (NAAT) testing for screening for viral infection and single-antigen beads for Human Leukocyte Antigen (HLA) antibody detection have played major roles in the development of organ transplantation. This chapter reviews the mechanisms of action, clinical evidence-based use, and the adverse reactions associated with commonly used immunosuppressive agents.

IMMUNOSUPPRESSIVE STRATEGIES

Immunosuppressive strategies must balance the risk of an acute rejection episode with its short- and long-term negative consequences on graft function and survival, the side effects of both long-term
immunosuppression on infectious complications and the increased risk of cancers, as well as the individual side effects of the immunosuppressive agents. The relative importance of each factor may vary depending on the organ transplanted. For example, for kidney recipients, an acute rejection episode, possibly antibody-mediated rejection, is a major risk factor for chronic rejection; strategies focus on minimizing the incidence of acute rejection episodes. For liver recipients, an acute rejection episode is usually easily reversed and has little long-term significance; therefore, lower initial doses of immunosuppression can be used and then increased in those patients who suffer a rejection episode. Dialysis can provide backup organ function support if a kidney graft fails, whereas there is no recourse (other than a retransplant) for failure of many other solid-organ grafts. Therefore, particularly for heart and lung recipients, early aggressive immunosuppressive strategies are warranted.

Thus, no single approach applies uniformly across all organs to posttransplant immunosuppressive therapy. Immunosuppressive agents can be categorized according to their use: induction—those used for a limited interval at the time of transplant; maintenance—those used long term for maintenance of immunosuppression; and antirejection—those used for a short time or in high doses to reverse an acute rejection episode. Considerable overlap exists among these categories, however. For example, the monoclonal and polyclonal antibodies can be used for induction or rejection treatment; steroids are used in high doses for induction or antirejection therapy but in lower doses for maintenance therapy.

Finally, many transplant programs individualize immunosuppression depending on the perceived immunologic risk of rejection and graft loss for that recipient. For example, for kidney recipients, immunosuppressive protocols at a single center may vary for a perfectly matched living donor recipients, low-risk cadaver donor recipients, and high risk recipients (e.g., blacks, those with a high panel-reactive antibodies or delayed graft function, or retransplant recipients).

**Induction**

All recipients (except for identical-twin recipients or those fully chimeric following a bone marrow transplant from the same donor) require immunosuppressive therapy at the time of transplantation. Many transplant centers begin with the same immunosuppression that is used for long-term maintenance. Other centers begin using induction therapy with polyclonal (e.g., thymoglobulin, ATGAM) or monoclonal (e.g., basiliximab, alemtuzumab) antibodies. The purpose of induction immunosuppression is to provide powerful immunosuppression at the time of antigen exposure, with the goal of reduction of the overall
incidence of rejection, and if needed, permit a delay in introducing other maintenance agents such as calcineurin inhibitors (CNIs; tacrolimus [TAC] and cyclosporine [CSA]) that may add to graft dysfunction. The frequency of acute rejection episodes is reduced with induction therapy; however, they are expensive, and a long-term benefit has not been well documented for low-risk recipients, although the risk for posttransplant proliferative disorder (PTLD) and viral infections are increased.

Maintenance Therapy

With the introduction of multiple new agents in the 1990s, immunosuppressive protocols have become more varied. At most centers, CNIs form the basis of immunosuppressive protocols. These drugs have been used as monotherapy and/or in combination with PRED or an antimetabolite. Prospective randomized trials have shown a lower incidence of acute rejection when mycophenolate mofetil (MMF) replaces azathioprine (AZA) in these combination protocols [2–4].

Of interest, CNI-free protocols have been devised. The major goal of such protocols is to avoid the nephrotoxicity associated with use of CNIs. The combination of sirolimus (SRL) and MMF has been used to achieve these results. Although nephrotoxicity can be avoided, relatively high doses of both drugs need to be used; as discussed previously, they each have their own side effects and is also associated with high incidence of acute rejection. In other randomized trials of CNI-free protocols, belatacept [5–7] and tofacitinib [8,9] have been used.
PHARMACOLOGIC AGENTS

Calcineurin Inhibitors

Cyclosporine and TAC, although structurally dissimilar, have a similar mechanism of action. Both drugs interfere with the cellular pathway for cytokine production and T-cell proliferation. The protein calcineurin has been validated as part of the calcium-dependent signal transduction pathway of interleukin-2 (IL-2) production in T cells [10]. CSA and TAC bind to two intracellular receptors, CypA and FKBP12, respectively; these receptors are found in virtually all cell types. The resulting receptor complex binds to calcineurin, blocking its phosphatase ability and thereby interrupting the production of IL-2 [10].

Cyclosporine

CSA was isolated from a soil sample in Norway and produced by the fungus *Tolypocladium inflatum*. The first formulation of CSA that was approved by the U.S. Food and Drug Administration (FDA) in 1983 was Sandimmune; this was modified to the microemulsion (ME) formulation called Neoral and was approved by the FDA in 1995.

CSA is a lipophilic decapeptide, consisting of several amino acids in a ring structure. The original oral formulation (Sandimmune) is dependent on the presence of bile in the upper small intestine, which makes it problematic for liver transplant recipients. Neoral self-emulsifies in water, making absorption much more reliable [11]. The side-effect profiles were unchanged. The oral bioavailability of the ME-CSA is approximately 30%. The average half-life of CSA ranges from 6 to 9 hours. It is extensively metabolized by the liver to multiple metabolites via the cytochrome P450 3A4 enzyme system. Significant liver impairment can slow the clearance of CSA by the body. Because very little drug is eliminated by the kidney, renal failure does not change CSA elimination [12].

The extensive side-effect profile of CSA has long been a reason for attempts at minimizing drug exposure. Of most concern is its acute and chronic nephrotoxicity. Acute nephrotoxicity from CSA is initially characterized by vasoconstriction of the intrarenal arterioles, resulting in a reduced glomerular filtration rate [13]. CSA-induced thrombotic microangiopathy (TMA) was first reported in liver allograft recipients.
and then in kidney and heart recipients [14]. TMA can present as a full-blown syndrome consisting of hemolytic anemia, thrombocytopenia, neurologic abnormalities, fever, and renal failure. Discontinuation of CSA is an important step in management along with plasmapheresis and fresh frozen plasma replacement. TAC or SRL can be substituted as immunosuppressive agents, although TMA can occur with either of these agents. Even in extrarenal transplant recipients, the effect of CSA on long-term kidney function can be significant, leading to proteinuria and end-stage renal disease (ESRD) [15]. Kidney biopsies of their native kidneys reveal wrinkling and thickening of the glomerular basement membrane, with some kidneys exhibiting microthrombotic angiopathy and fibrosis. Most patients receiving CSA develop hypertension, sometimes requiring multiple drug therapy. The mechanism for CSA-induced hypertension is primarily related to small-vessel vasoconstriction, in part by increased endothelin production. Treatment of hypertension has focused on calcium-channel blocker use because calcium-channel activation induces endothelin vasoconstriction and increases blood pressure. CSA has been associated with several neurologic toxicities, including headaches, tremors, seizures, and encephalopathy. Reversible posterior leukoencephalopathy can occur after CSA use and affects the posterior white matter and the frontal lobes and gray matter [16]. It manifests with confusion, coma, cortical blindness, cerebellar syndrome, hemiplegia, and flaccid paralysis or various combinations of these features. Hypertrichosis and gingival hyperplasia can reduce patient compliance to CSA. Electrolyte imbalances may occur with CSA, including hyperkalemia, hyperuricemia, and hypomagnesemia. CSA can increase cholesterol and triglyceride levels, sometimes requiring treatment with lipid-lowering medications [12].

CSA is metabolized by the cytochrome P450 3A4 enzyme system that is found not only in the liver but also in the cells lining the intestine; so CSA levels can be increased or decreased by changes in gut absorption or in liver metabolism [17]. Most centers initiate CSA therapy at 4 to 8 mg/kg/d orally, starting the day after transplant. If the transplanted kidney shows signs of delayed graft function (DGF), the initiation of CSA may be delayed. Monitoring CSA levels is vital because of its narrow therapeutic window.

**Tacrolimus**

With the success of CSA, researchers studied soil samples from around the world, looking for another compound that might turn out to display immunosuppressive properties. TAC, initially known as FK-506, was isolated from a soil sample in Tsukuba, Japan, in May 1984, from the
fungus *Streptomyces tsukubaensis* [18] and was FDA approved in 1994. It has a completely different chemical structure from CSA, yet its effect on the lymphocyte is remarkably similar. A few differences have been found on the cellular level between CSA and TAC. The FKBP12-TAC complex is 10 to 100 times as potent as CSA, possibly because of greater affinity for its binding protein [19].

The pharmacokinetic profile of TAC is similar to that of CSA. TAC has an extremely lipophilic, macrocytic lactone structure. Its oral bioavailability ranges anywhere from 4% to 93% (average 25%). One significant difference between CSA and TAC is that with TAC the presence or absence of bile in the digestive tract does not significantly alter absorption. The metabolism is also similar to CSA, with the cytochrome P450 3A4 system as the primary metabolic pathway. The elimination half-life ranges from 8 to 20 hours, depending on the population studied [20].

The adverse event profile of TAC is similar to CSA in many respects. TAC appears to have the same nephrotoxicity seen with CSA, and the mechanism also appears to be the same. However, in one study, mean or median serum creatinine levels in renal transplant recipients were lower in TAC-treated patients, with 5-year follow-up, than in patients treated with CSA-ME [21]. As with CSA, the nephrotoxicity of TAC is concentration dependent, making drug level monitoring equally important [22]. Hypertension has also been reported with TAC. Immunosuppression with TAC-based regimens is associated with better lipid profiles than is immunosuppression with CSA-based regimens. Neurotoxicity appears to be somewhat worse than with CSA; headache, tremor, neuropathy, seizures, blindness, coma, and various other neurologic complaints have been seen with TAC [23]. Patients usually recover when the drug is stopped. The incidence of hyperkalemia appears to be similar to that with CSA, although hypomagnesemia is more likely to occur with TAC-treated patients [24]. TAC-associated TMA has a reported incidence between 1% and 4.7% [25]. The incidence of posttransplant diabetes mellitus (PTDM) was significantly higher among TAC-treated patients than among CSA-treated patients (9.8% vs. 2.7%) according to a meta-analysis [26]. Many patients with PTDM have reversal of diabetes mellitus, with eventual discontinuation of insulin. In a U.S. trial combining TAC with MMF and corticosteroids, the 10-year incidence was 6.5%, and the 1-year prevalence was 2.2% [27].

TAC is metabolized through the same pathway as CSA and has been subject to the same interactions with the cytochrome P450 3A4 system. As with CSA, careful blood concentration monitoring is required; TAC also has a narrow therapeutic range. The current suggested therapeutic range for TAC is 5 to 20 ng per mL; however, this range is still controversial and under study [19]. TAC is usually initiated at a dose of
0.05 to 0.10 mg/kg/d. Some centers, including ours, use a standard starting dose of 2 mg PO BID and adjust doses on the basis of subsequent trough levels. As with CSA, TAC may be delayed after a kidney transplant in the presence of DGF, especially under the cover of induction therapy.

In studies of TAC and CSA in kidney recipients, results have been similar to those with liver recipients (i.e., same graft and patient survival rates, fewer rejection episodes) [28]. This pattern has also been seen in higher-risk patient populations, such as black recipients [29]. Other transplant categories with historically higher rates of rejection, such as pancreas transplant recipients, have seen benefit with TAC-based immunosuppressive regimens [24]. TAC continues to be the primary maintenance immunosuppressive agent in heart, lung, and bowel recipients and was approved by the FDA for heart transplantation in 2006 [30–33].

Recently, two formulations of tacrolimus with daily administration were approved by the FDA. Astagraf XL, and extended-release capsule, was approved in 2013 for kidney transplant recipients also receiving Mycophenolate Mofetil (MMF) and prednisone (PRED). Envarsus XL was FDA approved in July 2015 for maintenance immunosuppression (IS) after conversion from once-daily tacrolimus. It is possible that extended-release formulations have improved side-effect profile and bioavailability [34]. Phase IV evaluation will further determine their impact on graft and patient survival.

**Antiproliferative Agents**

Antiproliferative agents have been part of transplant protocols since the first transplant was performed in the 1960s. Early antiproliferative agents included radiation, azaserine, actinomycin D, and cyclophosphamide. AZA, developed in the early 1960s, was part of the first successful transplant series reported in 1963. It continues to be used today in maintenance immunosuppressive regimens and for autoimmune diseases. A major advance in antiproliferative agents has been the development and use of MMF, released for clinical use in 1995. MMF is now a component of most new transplant regimens.

**Azathioprine**

AZA is a prodrug of 6-mercaptopurine, which interrupts the de novo purine synthesis, leading to inhibition of leukocyte function. It is rapidly
absorbed after oral administration, and metabolized by xanthine oxidase and excreted into the kidneys. AZA is relatively well tolerated by most patients. The most common side effect is dose-dependent myelosuppression usually limited to the white blood cells, but occasionally red cell aplasia is observed. Liver function tests must be regularly monitored: AZA has been reported to cause hepatic necrosis and liver failure. Pancreatitis or a skin rash may indicate an allergic reaction, in which case AZA may need to be stopped. Hair loss is bothersome to some patients but is reversible. Gastrointestinal (GI) disturbances, including nausea and vomiting, are mild and usually tolerable. Most recipients are maintained on a daily dose of 1.0 to 2.5 mg per kg. Some centers switched all their recipients when MMF became available, but some are still maintained on AZA because of a significant cost advantage over MMF, or because of improved GI toxicity profile.

**Mycophenolate Acid**

MMF (CellCept) was approved by the FDA in 1995 to prevent rejection in kidney recipients. Its use has grown to include liver, heart, lung, and pancreas recipients. It has been a major addition to the immunosuppressive arsenal. MMF is also a prodrug, quickly metabolized to the active compound, mycophenolic acid (MPA). In 2004, Myfortic (EC-MPA) an enteric-coated formulation of MPA was FDA approved. MPA acts as a noncompetitive inhibitor of inosine monophosphate dehydrogenase, thereby blocking de novo purine synthesis \(^{[35]}\). The oral bioavailability for MPA approaches 100% and is primarily excreted in the urine.

MMF can cause significant GI problems, including nausea, vomiting, diarrhea, abdominal pain, and gastroesophageal reflux. Persistent diarrhea not accompanied by fever may be associated with an erosive enterocolitis causing malabsorption of nutrients that has been attributed to a toxic action of the acyl mycophenolic acid glucuronide (MPAG) metabolite on absorptive cells \(^{[36]}\). Dividing the total daily dose into four doses instead of two may be effective in reducing GI problems in some recipients. EC-MPA was developed to mitigate the GI toxicities; patients who had GI intolerance on MMF administration required fewer dose changes of EC-MPA \(^{[37]}\). Neutropenia and thrombocytopenia can also occur with MPA, requiring a dosage reduction. At 2 g daily, the occurrence rate in the major trials was comparable to AZA. Coadministration with CSA lowers MPA concentrations \(^{[38]}\). In contrast, coadministration with TAC tends to increase MPA levels because of inhibition of MPA metabolism \(^{[39]}\). Cholestyramine, a bile acid resin, decreases cholesterol by interfering with its enterohepatic cycling and decreases the total area under the curve (AUC) by 40%, and antacids

...
reduce absorption of MMF by 20%.

The success of MPA has allowed it to generally replace AZA in many transplant centers. The results of three major trials were instrumental. The U.S., Tricontinental, and European trials compared MMF, in combination with CSA and steroids, with conventional immunosuppression. The U.S. and Tricontinental trials randomized patients to MMF at a low (2 g per day) or high dose (3 g per day) versus AZA, whereas the European study used a placebo instead of AZA [2–4]. All three trials saw significantly reduced rejection in the MMF arm at 6 months posttransplant. Whether long-term MMF changes survival rates is still controversial. The 3-year data from the U.S. trial periods do not yet show a statistically significant difference in patient or graft survival [2]. A European study using the ME-CSA showed only modest, insignificant reductions in acute rejection episodes with MMF compared with AZA, questioning the value of using the costlier MMF [40]. These findings, which are drawn on low-immunologic-risk patients, ought to be applied cautiously in other situations. A subgroup analysis of the higher immunologic-risk African American patients enrolled in the U.S. pivotal trial showed that the benefit for African American versus White recipients was restricted to the MMF 3 g dose versus the MMF 2 g dose or azathioprine cohorts [41]. Thus, African American recipients should receive 3 g per day unless they are unable to tolerate that dose. In a multicenter trial, using a combination of TAC with MMF, an MMF dose of 2 g per day reduced the incidence of acute rejection episodes compared with MMF 1 g per day or AZA—the low acute rejection rate of 8.6% using a combination with MMF 2 g per day suggest that a combination with TAC produced superior results compared with a combination with CSA [42]. EC-MPA was demonstrated to be therapeutically equivalent to MMF [43]. The combination of TAC and MMF is the most prevalent in the United States; in 2013, almost 95% of patients were maintained on this combination [44]. Based on initial pharmacokinetics studies, MMF doses have not been based on recipient body weight [45]. Determination of MPA levels is not clinical routine.

**Sirolimus**

Sirolimus (formerly known as rapamycin) belongs to a class of compounds known as the mammalian target of rapamycin (mTOR) inhibitors and was approved in 1999 to prevent rejection in kidney recipients. It is produced by *Streptomyces hygroscopicus*, a fungus isolated from a soil sample found on Easter Island (Rapa Nui). SRL was the first mTOR inhibitor to be approved in the United States. A derivative of rapamycin, everolimus, was approved by the FDA in 2004. SRL binds to FKBP-12, the same binding protein as TAC; however, the target of SRL
is not calcineurin, but rather the target protein mTOR [46]. The inhibition of mTOR prevents cell-cycle progression from G1 to S in T lymphocytes; thus, SRL blocks the rejection pathway at a later stage than CSA or TAC [47]. It is rapidly absorbed, but the systemic bioavailability of the current formulation is only approximately 15%. The primary pathway for metabolism is the cytochrome P450 3A4 enzyme system. SRL has a much longer half-life than CSA or TAC, with an average terminal half-life of approximately 60 hours, allowing it to be dosed daily.

SRL has a different profile of adverse events than other immunosuppressive drugs. It is less kidney-toxic and diabetogenic than CSA or TAC. TMA may also occur [48]. Proteinuria is a common manifestation of SRL toxicity in patients converted from CNI for renal impairment. Preexisting renal damage may be necessary before proteinuria manifests, but it is reversible [49]. Hypertriglyceridemia and hypercholesterolemia are dose-related adverse events of SRL that may be exacerbated by the use of steroids or CNI [50]. Fifty-three percent of SRL-treated patients required lipid-lowering agents compared with 24% in the CSA group. SRL causes dose-dependent thrombocytopenia and leukopenia, particularly during initial therapy; their incidence is variable and usually self-limiting; usually only at supertherapeutic serum concentrations ≥16 ng per mL [51]. The incidence of anemia is also increased with the use of mTOR inhibitors and was observed in 16% of recipients taking 2 mg per day and 27% of recipients taking 5 mg per day of SRL [52]. During clinical trials, other adverse events associated with SRL included hypertension, rash, acne, hypokalemia, diarrhea, aphthous ulcers, and arthralgias [53]. Interstitial pneumonitis can occur any time after SRL treatment; mortality up to 12% has been described [54]. Other common adverse effects that occur with de novo SRL use in transplant recipients include wound-healing problems and lymphoceles [55]. Most of the drug interactions that have been reported for SRL are related to P450 enzyme inhibition or induction—the same list of drugs that interact with CSA and TAC. SRL, like TAC, also increases exposure to MPA.

The phase II trials conducted in Europe were among the earliest that used SRL as a principal immunosuppressant. Higher glomerular filtration rates and similar rejection rates were seen in patients receiving SRL as compared with CSA [56,57]. The two large phase III studies of SRL, one conducted in the United States [58] and the second worldwide [52], revealed much about how best to use SRL and its drawbacks: higher incidence of lymphocele formation and wound infections. It was also found that the renal function of patients on a combination of SRL and
CSA was worse than patients on CSA alone. Regarding the combination of SRL with TAC, registry data suggest poorer graft survival compared with the combination of TAC with MMF [59]. Phase III studies indicated that the combination of either 1.5 mg per day or 3 mg per day of everolimus was better than MMF in the prevention of acute renal allograft rejection when combined with CSA and steroids after kidney transplantation. The combination of everolimus/CSA was associated with poorer renal function than MMF/CSA combination [60].

Inhibitors of mTOR are known to prevent tumor cell growth. Temsirolimus (and in some cases everolimus), both SRL derivatives, have been used in clinical trials of advanced renal carcinoma, breast cancer, prostate cancer, pancreatic cancer, glioblastoma, and lymphoma. A multivariate analysis of posttransplant malignancies in renal allograft recipients showed a lower incidence of malignancy in patients taking mTOR inhibitors alone or in combination with CNI compared with those taking CNI alone [61]. SRL has also been found to be effective in the treatment of posttransplant lymphoproliferative disorder (PTLD) [62] and Kaposi sarcoma [63]. It is also used to limit scarring on coronary stents. Because of its efficacy/side-effect profile, the clinical use of mTOR inhibitors has decreased from about 20% of kidney recipients in the early 2000s to about 5% of recipients at 1 year posttransplant [44]. Drug level monitoring is important, especially in newer protocols that may not contain CNI or steroids; target trough levels are between 5 and 15 ng per mL.

Corticosteroids

Steroids have been a part of transplantation since its inception. It soon became clear, however, that the toxicities of steroids could overshadow their benefits. The role of steroids in transplantation is changing, as experience is gained in the use of newer immunosuppressive medications that are serving to limit corticosteroid use. Steroids have many different effects on the immune system; they inhibit T-cell proliferation, T-cell–dependent immunity, and the expression of various cytokines, especially IL-2, IL-6, interferon-γ, and tumor necrosis factor-α (TNF-α) [64]. They also suppress antibody formation and the delayed hypersensitivity response found in allograft rejection [65].

For years, steroids have been part of any immunosuppressive regimen to prevent and treat rejection. For use in standard immunosuppression, recipients typically begin on a high initial dose (up to 500 mg IV of methylprednisolone [MP]) on the day of the transplant and then taper over weeks to months to their final maintenance dose. Some centers maintain recipients on 5 to 10 mg daily. Steroids at high doses have successfully reversed rejection episodes [66]. Most centers use 250 to
500 mg of IV MP for three (or more) doses to reverse a suspected or documented rejection episode. Steroid use is associated with a number of problems, acute and long-term, and typically dose-dependent. Acute toxicities of corticosteroids include sodium retention, glucose intolerance, mental status changes, and increase in appetite, acne, and gastritis. The long-term side effects include cataracts, hypertension, osteoporosis, and diabetes. Hypertension, hyperlipidemia, and steroid-induced diabetes may be partly responsible for increasing the risk of cardiovascular death in transplant recipients. Accordingly, many transplant centers are switching to steroid-withdrawal/steroid-free protocols for many of their recipients.

A meta-analysis of trials where steroid withdrawal had been done in the first year after kidney transplantation showed that although the risk of acute rejection was more than twofold when steroids were withdrawn, there was no significant difference in the incidence of graft failure [67]. The European TAC/MMF study group randomly assigned immunologically low-risk patients who had undergone transplantation 3 months earlier to continue triple therapy (TAC, MMF, and steroids), withdraw steroid, or withdraw MMF. Incidence of acute rejection was similar in all three groups at 6 months [68], suggesting TAC enables more effective steroid sparing than does CSA. Graft and patient survival and the incidence of acute rejection were similar between groups at 3 years, and serum creatinine levels remained stable [69]. A 3-year analysis of a large trial was done of 300 patients receiving basiliximab induction, CNI, and MMF or SRL in which patients were assigned to have steroids withdrawn on day 2 or to continue steroids. No difference was noted in graft function, patient and graft survival, biopsy-proven acute rejection, or chronic allograft nephropathy between the two groups [70]. Use of MMF or SRL, with a CNI, may allow safe early withdrawal of steroids.
Various antibody preparations, both of polyclonal and monoclonal origin, are currently used in clinical immunosuppression. Polyclonal antibodies directed against lymphocytes were developed first and have been used in transplantation since the 1960s. The production of monoclonal antibodies was later made possible, and, in turn, allowed for the development of targeted therapy. A number of different monoclonal antibodies (mAbs) are currently under development or in various phases of clinical testing; several have been tested and are now in clinical use.

One disadvantage of early murine-based antibody preparations such as OKT3 is the potential for the development of antimouse antibodies by the recipient—antibodies that may then limit further use of the agent. To address this problem, recent efforts have focused on the development of so-called humanized versions of mAbs, either by replacing the murine constant portion (Fc) with a human Fc component, and/or by replacing the hypervariable region of the antibody that determines antigen specificity, thus in both instances creating a chimeric antibody. The remainder of the original murine antibody is replaced by human immunoglobulin G. The advantages of these humanized mAbs are a very long half-life, reduced immunogenicity, and the potential for indefinite and repeated use to confer effects over months rather than days [71]. Owing to their efficacy, biologic induction agents are currently used in about 85% of all kidney transplants in the United States [44].

Polyclonal Antibodies

Polyclonal preparations consist of a wide variety of antibodies and detect specificities including many T-cell molecules involved in antigen recognition. After administration, the transplant recipient’s total lymphocyte count will fall, and hence these are known as depleting antibodies. Lymphocytes, especially T cells, are then lysed and cleared from the circulation. Alternatively, their surface antigen may be covered by the antibody. Polyclonal antibodies have been successfully used to prevent rejection and to treat acute rejection episodes. Two main polyclonal antibody agents are available for clinical use in the United States: ATGAM and thymoglobulin.
ATGAM

ATGAM is obtained by immunizing horses with human thymocytes. It is generally administered at a dose of 10 to 15 mg per kg, in a course lasting 7 to 14 days. ATGAM must generally be infused into a central vein because infusion into a peripheral vein is often associated with thrombophlebitis. To avoid the cytokine release syndrome, recipients should be premedicated with MP and diphenhydramine hydrochloride. Side effects include fever, chills, arthralgia, thrombocytopenia, leukopenia, and a serum sickness–like illness. These side effects are more likely related to the release of pyrogenic cytokines such as TNF-α, IL-1, and IL-6, which result from cell lysis due to antibody binding to targeted cellular surface receptors [72]. Increased infection rates are associated with all immunosuppressants, but certain infections, such as cytomegalovirus, are more common after the use of ATGAM and other antibody preparations [73].

Thymoglobulin

Thymoglobulin (ATG) is obtained by immunizing rabbits with human thymocytes. Initial kidney transplant studies show ATG to be statistically superior to ATGAM in preventing acute rejection episodes and in reversing acute rejection episodes [74,75]. Administration before reperfusion is advocated to maximize antiadhesion molecule effects. The side-effect profiles of ATG and ATGAM are similar. With ATG, leukopenia and thrombocytopenia may be quite significant. If a significant drop in platelets or white blood cells is noted, the dosage should be halved or the drug temporarily withheld.

Monoclonal Antibodies

The hybridization of murine antibody–secreting B lymphocytes with a nonsecreting myeloma cell line produces mAbs. A number of mAbs are active against different stages of the immune response.

OKT3

OKT3 was the first monoclonal to be approved by the FDA in 1986. In 2010, the producer, Janssen-Cilag Inc., announced its withdrawal because of lack of sales. The description herein, therefore, will be brief, but it warrants discussion owing to its historical importance. OKT3 binds to CD3 on T cells, and complement-mediated cell lysis and antibody-dependent cell cytotoxicity, leading to rapid clearance of T cells (~95%) from the peripheral circulation [71]. OKT3 was used to treat biopsy-
proven acute rejections in patients with steroid-resistant acute rejection associated with vasculitis [76], and also as an induction agent. Human antimouse antibodies developed in at least 30% of patients, which rendered OKT3 ineffective, allowing for the reappearance of CD3+ T cells in the circulation. This scenario is more common with retreatment using OKT3 or with prolonged treatment. A marked cytokine release syndrome was the most common adverse effect. The most serious side effect was a rapidly developing, noncardiogenic pulmonary edema that could be life threatening. It was also associated with a wide spectrum of neurologic complications (headache, aseptic meningitis, and encephalopathy). Nephrotoxicity could also occur, as well as allograft thrombosis, infections (especially with cytomegalovirus), and PTLD.

**Anti–Interleukin-2 Monoclonal Antibodies**

IL-2 is a cytokine required for the proliferation of cytotoxic T cells. Two mAbs were developed to target the IL-2 receptor α-chain (IL-2Rα; CD25); daclizumab (Zenapax) was FDA approved in 1997, and basiliximab (Simulect) the following year. Daclizumab was withdrawn from clinical use in 2009, leaving basiliximab the only available agent for clinical use. Basiliximab is humanized (75% of the antibody is of human origin), the half-life of which is about 7 days.

Clinical trials in kidney recipients have shown these agents to be effective in preventing acute rejection [77], but it is not indicated for the treatment of acute rejection episodes. For basiliximab, two IV doses of 20 mg (one administered preoperatively and the other on postoperative day 4) are recommended. Comparable outcomes have been seen in studies comparing basiliximab and polyclonal antibodies and maintenance immunosuppression regimens consisting of CSA, MMF, and steroids [78]. Steroid-free maintenance regimens have also been used in kidney transplantation with anti-CD25 induction [79]. In all clinical trials to date, basiliximab has been shown to be remarkably safe, with minimal side effects ascribed directly to its use.

**Alemtuzumab (Campath)**

The CD52-specific humanized monoclonal antibody alemtuzumab has the advantages of ease of administration, consistency of monoclonal antibodies, and the benefits of humanization. Alemtuzumab rapidly and durably depletes CD52 expressing lymphocytes centrally and peripherally, resulting in near-total T-cell depletion with lesser depletion of B cells and monocytes [80]. It stopped from being commercially available for transplantation in September 2012, but remains available for appropriate patients via the producer (Genzyme). Alemtuzumab is
currently being marketed as Lemtrada for the indication of multiple sclerosis.

Although alemtuzumab depletes all T-cell subsets, its action is selective for naive cell types [81]. The T cells that are not depleted exhibit a memory phenotype and are most susceptible to CNI. Maintenance regimens using CNI work best following alemtuzumab induction. Alemtuzumab facilitates reduced-maintenance immunosuppression requirements, without an increase in infections or malignant complications in kidney, pancreas, lung, and liver transplantations as compared with historical controls [82–86].

**Rituximab (Humanized Anti-CD20)**

This is a chimeric monoclonal antibody specific for CD20, a cell-surface glycoprotein present on B cells (from pre-B cells, but not on terminally differentiated B cells). Rituximab rapidly clears CD20+ cells from the circulation.

Rituximab has been used as an induction agent in lieu of recipient splenectomy in patients undergoing donor desensitization with plasmapheresis and/or intravenous immunoglobulin [87]. Use of rituximab in high-grade rejection remains investigational. Rituximab has a role in the treatment of Banff 2 and 3 rejection and in reducing antibody formations [88]. A recent review indicated the paucity of data supporting its use in transplantation [89].

The most important indication for the area of rituximab in organ transplantation is as treatment of PTLD, as part of R-CHOP chemotherapy.

**Fusion Proteins**

These are made by the fusion of a single receptor targeting a ligand of interest with a secondary molecule, which is typically the Fc portion of an IgG molecule. Fusion proteins can be composed of humanized components limiting their immune clearance and allowing prolonged administration.

**Costimulation-Based Agents**

Costimulatory molecules alter the threshold for activation of naive T lymphocytes without having a primary activating or inhibitory function.
Fusion proteins have been developed that act by blocking costimulation pathways. The two costimulatory receptors on T cells are CD28 and CD152; these serve reciprocal roles—CD28 facilitates a T-cell response, whereas CD152 reduces it. The fusion proteins that act by inhibiting costimulation-based pathways, and have been studied in renal transplantation, inhibit CD28 and CD152 signaling, and this leads to immunosuppression.

Belatacept (investigative name LEA29Y) is a second-generation (first generation being Abatacept) costimulation-blockade agent that has two amino acid substitutions that give slower dissociation rate for binding to the ligands of CD28. The BENEFIT study reported the primary outcomes from a randomized, phase III study of belatacept versus CSA in kidney transplant recipients [5]. At 12 months, belatacept regimes demonstrated superior renal function and similar patient/graft survival versus CSA, despite an increase in acute rejection in the early posttransplant period. It has also been studies in recipients of extended criteria donor organs [6]. Belatacept is a promising, nonnephrotoxic option in kidney transplant recipients and is being developed with the aim of providing CNI avoidance [90]. It was tested as maintenance together with sirolimus (SIR) (attempted wean at 1 year) immunosuppression in low-risk patients with or without donor bone marrow and Campath induction [7]. The role of bone marrow was not established, but rejection was avoided, in this CNI-free regimen.

It is intended for use as an induction agent as well as for maintenance immunosuppression, but may have increased risk of acute rejection. Belatacept use has been limited owing to cost, monthly IV infusions, and high incidence of acute rejection, especially grade 2 and above.
OTHER IMMUNOSUPPRESSIVE AGENTS

Janus Kinase 3 Inhibitors

Janus kinase 3 (JAK3) is essential for the signal transduction from the cytokine receptors of several cytokines to the nucleus. Being expressed only on immune cell makes it an important target for developing new immunosuppressants. Several JAK3 inhibitors are available, but tofacitinib (CP-690550) is the most potent and selective JAK3 inhibitor. In vivo effects of tofacitinib include reduction in natural killer cell and T-cell numbers, although CD8+ effector memory T cells were unchanged [8]. A randomized, pilot study compared tofacitinib (15 mg BID [CP15] and 30 mg BID [CP30], n = 20 each) with TAC (n = 21) in de novo kidney transplant recipients [91]. Patients received an IL-2R antagonist, MMF, and steroids. Coadministration of tofacitinib 30 mg BID with MMF was associated with overimmunosuppression. At a dose of 15 mg BID, the efficacy/safety profile was comparable to TAC, although there was a higher rate of viral infection. A recent analysis of previous results demonstrated that patients with lower tofacitinib exposure maintained improved renal function, improved chronic changes on biopsy (IF/TA), and reduced biopsy-proven rejection than did the CSA group [9].
CONCLUSIONS

Since 1992, following the introduction of a number of new immunosuppressive agents, short-term graft and patient outcomes improved considerably. However, the side effect of immunosuppressive agents continues to present a major problem. With the increasing use of TAC, steroid-free protocols were used successfully. In kidney transplantation, long-term outcomes have been affected by the nephrotoxicity of CNI. In nonrenal transplant recipients, CNI toxicity has led to renal insufficiency and failure in a significant number of instances. Development of nonnephrotoxic agents like SRL, MMF, belatacept, and JAK3 inhibitors and their use in combination will someday lead to the successful use of CNI-free immunosuppression. A summary of some of the advances in the field of immunosuppression is shown in Table 63.1.

Another major advantage of the availability of several immunosuppressive agents is that immunosuppression can now be tailored for the individual patient. Those having drug-specific toxicity can be switched to another drug with similar efficacy but differing side effects.
ACKNOWLEDGMENT

We are grateful to Melissa Connell for assistance with organizing the manuscript.
REFERENCES

Hematopoietic cell transplantation (HCT) is typically performed in patients with life-threatening disorders of the hematopoietic system. The procedure has considerable risks of transplant-related morbidity and mortality with a substantial proportion of patients requiring intensive medical care [1–3]. Thus, knowledge of the basic principles of the transplant procedure and an understanding of potential complications including their differential diagnosis are important for improving the outcomes of critically ill patients after transplantation.

HCT is potentially curative treatment for diseases including leukemia, lymphoma, myelodysplasia, multiple myeloma, aplastic anemia, hemoglobinopathies, and congenital immune deficiencies. In selected cases, HCT may also have a role in the treatment of solid tumors such as germ cell tumors, renal cell cancer, and breast cancer, and as a type of immunosuppression for patients with life-threatening autoimmune diseases (Table 64.1). In preparation for HCT, chemotherapy alone, or combined with irradiation therapy, is used to eradicate the underlying disease and to induce transient immunosuppression in the recipient to prevent graft rejection, a possible complication mediated by immunological host-versus-graft reactions after allogeneic HCT. Chemoradiation is followed by intravenous infusion of the graft, which contains hematopoietic stem cells (HSC) that home to the bone marrow and reconstitute the hematopoietic system of the patient. In contrast to autologous HCT, allogeneic HCT requires prophylactic immunosuppressive therapy after transplant to prevent or mitigate graft-
versus-host disease (GVHD), an inflammatory syndrome that primarily affects the skin, gastrointestinal (GI) tract, and liver.

Classification
HCT can be categorized according to the source of stem cells, the type of donor, or the intensity of the preparative regimen. The type of HCT used in an individual patient is a complex decision based on the patient’s age, diagnosis, disease stage, prior treatments, donor availability, and presence of comorbidities.

**Stem Cell Source**

HSCs capable of reconstituting hematopoiesis after HCT can be obtained from bone marrow, peripheral blood, or umbilical cord blood (UCB). The stem cell products obtained from each of these sources are characterized by distinct kinetics of engraftment and recovery of immune function after transplantation. These features may affect the risks of developing infectious complications and GVHD during the posttransplant period.

**Bone Marrow.** Bone marrow was historically the most common source of stem cells for HCT but is now used very infrequently for autologous HCT. Bone marrow is harvested from the iliac crest under general anesthesia, from appropriate volunteer donors. Engraftment after bone marrow transplant is evidenced by rising neutrophil and platelet counts and occurs between 3 and 4 weeks after transplant.

**“Mobilized” Peripheral Blood.** Growth factor–mobilized peripheral blood stem cells (PBSCs) are the predominant source of HSC for allogeneic HCT in adults and are almost always used as HSC rescue for autologous HCT [4]. Engraftment after PBSC transplantation occurs approximately 1 week earlier compared with bone marrow transplantation. PBSC allografts contain approximately 10 times more T cells than do marrow, which influences the development of GVHD, graft rejection, and rate of relapse for malignancies after HCT. Randomized studies have shown a higher risk for relapse and lower risk for chronic GVHD among recipients of marrow compared with PBSC [5,6].

**Umbilical Cord Blood.** UCB contains HSC sufficient for reconstitution of hematopoiesis, which can be collected from the placenta and umbilical cord immediately after delivery of a baby. T cells contained in UCB are immunologically naive, which allows for less stringent human leukocyte antigen (HLA) matching between donor and recipient. There generally are smaller numbers of HSC in a typical UCB unit compared with bone marrow or PBSC harvest, which may increase the possibility for delayed engraftment, graft rejection, or infection [7,8]. The infusion of two UCB units appears to mitigate the risk for graft rejection, in part by increasing the total number of HSC delivered to the patient [9].

**Donor Type**
**Autologous.** Transplantation of HSC donated by the patient is termed *autologous HCT*. Most commonly, autologous PBSC are cryopreserved and then thawed and reinfused once the high-dose preparative therapy has been completed. High-dose chemoradiation is given to kill tumor cells that may not be susceptible to conventional-dose cytotoxic therapy. The success of the autologous transplant procedures relies exclusively on the tumor-eradicating potential of the preparative regimen [10]. The effect the conditioning regimen has on extrahematopoietic tissues determines the dose-limiting toxicity of the procedure. Relapse after autologous HCT may occur from tumor cells that have survived the conditioning therapy or from those that contaminated the graft, although the former mechanism appears to be more important.

**Syngeneic.** Transplantation of HSCs donated from identical (monozygotic) twins is termed *syngeneic HCT*. When there is no genetic disparity between donor and recipient, the biology of the transplant is similar to autologous HCT. Compared with allogeneic HCT from HLA-matched related or unrelated donors, relapse rates are higher after syngeneic HCT, which has been attributed to the absence of graft-versus-leukemia reactions.

**Allogeneic.** Transplantation of HSCs cells donated by another individual is termed *allogeneic HCT*. Allogeneic HCT requires availability of an HLA-compatible related or unrelated donor. Because of the inheritance pattern of HLA haplotypes, the statistical likelihood of two siblings being genotypically HLA identical is 25%. Donor-recipient HLA genotypic identity is associated with the lowest risks for immunologically mediated complications such as graft rejection and GVHD. For patients who do not have an HLA-identical sibling donor, approximately 70% of all patients, a search for a suitable unrelated donor can be considered. HCT from HLA-matched unrelated donors, however, has traditionally been associated with higher risks of transplant-related morbidity and mortality compared with HCT from HLA-identical related donors [11]. Use of unrelated donors who are matched using molecular HLA typing methods can improve outcomes considerably, and, for some diseases, survival of patients with unrelated grafts has approached that with HLA-identical sibling grafts [12,13]. Another alternative source of HSC is a haploidentical relative, such as a parent or child, defined by the inheritance of one identical haplotype and mismatching of one or more HLA loci with the noninherited haplotype. Over the past decade, technological advances have improved the outcome for recipients of HLA-disparate grafts. When more than a single HLA antigen disparity is present, depletion of T cells from the graft is necessary to prevent life-threatening GVHD. Depletion of T cells from the graft may be accomplished *ex vivo* by using immunologic or physical methods to
separate HSC from T cells, or in vivo by administering cyclophosphamide 3 to 4 days after the transplant [14,15]. Because T cells play an important role in establishment of the graft, early immune reconstitution, and tumor control, T-cell depletion has been associated with higher rates of graft failure, opportunistic infections, and relapse.

Intensity of the Preparative Regimen

Myeloablative. In myeloablative HCT, the preparative regimen ablates the hematopoietic system of the patient and leads to profound myelosuppression with pancytopenia. The transplanted HSC reconstitute the ablated hematopoietic system in the recipient. High-dose chemotherapy regimens, with or without doses of total body irradiation (TBI) that exceed 6 gray (Gy), combine different drug combinations that have nonadditive toxicities with radiation. The aim of high-dose therapy is to overcome the genetic heterogeneity of tumors by employing agents with different mechanisms of action. Although the myeloablative regimens used for autologous HCT typically consist of drugs that provide maximum tumor eradication with tolerable toxicity to the patient, regimens used for allogeneic HCT also must provide sufficient recipient immunosuppression to prevent graft rejection. Myeloablative preparative regimens are associated with substantial risks of transplant-related toxicity and mortality, particularly among older or medically ill patients [16]. Over the past decade, several “reduced-intensity conditioning” (RIC) regimens have been developed that combine lower doses of traditional conditioning agents or substitute less toxic agents, resulting in fewer complications after HCT, although in advanced leukemia the trade-off may be a greater rate of post-HCT relapse [17].

Nonmyeloablative. Nonmyeloablative preparative regimens for allogeneic HCT are mainly immunosuppressive and aimed at preventing graft rejection. The underlying malignancy is eliminated through the ensuing immunologic graft-versus-tumor effects, provided the tumor expresses antigens that make it a target for immune attack. Compared with myeloablative allogeneic HCT, the extrahematopoietic toxicity from nonmyeloablative preparative regimens is considerably milder, an important consideration for older patients or those with comorbidities [18]. Typical post-HCT complications such as GVHD and infections, however, are not prevented by nonmyeloablative conditioning but may have a delayed onset. Not only are RIC regimens highly immunosuppressive, but they also include agents that have marrow-
suppressive effects. RIC regimens are generally associated with less morbidity and mortality compared with myeloablative regimens, yet may have greater antitumor effect compared with nonmyeloablative regimens.

Epidemiology

During 2013 more than 21,000 HCT procedures were registered with the Center for International Blood and Marrow Transplant Research (CIBMTR), of which approximately 40% were allogeneic. Allogeneic HCT is most commonly performed in adults using PBSC grafts. In contrast, children now predominantly receive cord blood or marrow grafts (NMDP website: [http://www.marrow.org/](http://www.marrow.org/)). PBSC is less used in children because of the difficulties harvesting PBSC from young children and because of the increased risk of chronic GVHD.

Risk Factors for Transplant-Related Morbidity and Mortality

The likelihood of developing transplant-related complications depends on patient age, the intensity of the preparative regimen, the type and stage of the underlying disease, and the presence of comorbidities. Prognosis is most heavily influenced by the underlying disorder. Patients with chronic malignancies and nonmalignant disorders, such as aplastic anemia, have a higher likelihood of survival compared with those with aggressive malignancies, who have a greater tendency to relapse following HCT. Mortality caused by the transplant procedure, and not from disease relapse, termed transplant-related mortality, ranges from 15% to 40% for allogeneic HCT recipients compared with 5% to 10% for autologous HCT recipients. HLA disparity between donor and recipient increases the risk of transplant-related mortality owing to the greater likelihood of developing GVHD and graft rejection [13]. The risk for mortality increases significantly with age, although improvements in supportive care and donor selection and the introduction of nonmyeloablative preparative regimens have increased the proportion of patients older than 60 years who benefit from allogeneic HCT. Recent studies have demonstrated that pretransplant assessment of comorbidities using simple but transplant-specific comorbidity scoring systems has improved the ability to predict subsequent transplant-related mortality and survival [16,19].
TRANSPLANT-RELATED COMPLICATIONS

Transplant-related complications include infections, regimen-related toxicity, and alloimmune-mediated graft rejection and GVHD (Fig. 64.1). More intense conditioning regimens and higher degrees of donor-recipient HLA disparity are associated with greater risk for infection. Regimen-related toxicities include profound cytopenias and organ damage that follow myeloablative conditioning. The complications seen after allogeneic HCT that may occur irrespective of the intensity of the conditioning regimen include rejection, GVHD, and hemolysis.

**FIGURE 64.1** Complications after myeloablative allogeneic hematopoietic cell transplantation. BOOP, bronchiolitis obliterans with organizing pneumonia (also known as cryptogenic organizing pneumonia); DAH, diffuse alveolar hemorrhage; GVHD, graft-versus-host disease; HHV6, human herpes virus 6; HSV, herpes simplex virus; IPS, idiopathic pneumonia syndrome; SOS, sinusoidal obstruction syndrome.

**Regimen-Related Pancytopenia**

Reconstitution of hematopoiesis after HCT occurs in an orderly pattern;
in general, neutrophil recovery occurs first, followed by recovery of platelets and red blood cells (RBCs). The tempo of hematopoietic reconstitution varies according to the type of HSC product, being earlier after PBSC grafts and later after UCB grafts, compared with marrow grafts. Transfusions of platelets and RBCs often are needed until there is marrow recovery. Transfusion of RBCs should be determined by the clinical condition of the patient, including hemodynamic stability and presence of active hemorrhage. RBC transfusions generally are indicated when the hemoglobin falls below 8 g per dL. Platelet transfusions are indicated when the platelet count falls below 10,000 cells per µL to minimize the risk for spontaneous bleeding [20]. Transfusions thresholds should be increased before invasive procedures or in patients with bleeding to a level appropriate for any other intensive care unit patient. Platelet consumption may be increased in patients with fever, disseminated intravascular coagulation (DIC), sinusoidal obstruction syndrome (SOS), or splenomegaly. Patients who have become alloimmunized to platelet antigens demonstrate poor response to platelet transfusions and may achieve higher platelet counts by limiting the number of donor exposures, controlling fever or DIC, or use of nonpooled (single-donor) or HLA-matched platelets [21].

Precautions should be taken in preparation of blood products for transfusion into HCT patients because passenger lymphocytes may cause GVHD and latent viruses may be transferred through leukocytes. Except for the stem cell graft, all other blood product components should be irradiated at a dose of 1,500 to 3,000 cGy to inactivate or eliminate contaminating lymphocytes. Depletion of leukocytes or use of blood components that test seronegative for cytomegalovirus (CMV) are effective for prevention of CMV transmission to CMV-seronegative recipients [22]. Removal of white blood cells from platelet and RBC products also decreases the risk for alloimmunization of the patient.

Regimen-Related Toxicity

High-dose cytotoxic chemotherapy with or without doses of TBI exceeding 6 Gy may severely disrupt mucosal integrity and has the potential to cause regimen-related toxicity (RRT) in the skin, GI tract, liver, bladder, lung, heart, kidney, and nervous system. RRT occurs predominantly within the first 3 to 4 weeks after conditioning and is more common after myeloablative than RIC [23]. RRT increases the risk for opportunistic infection, which is already high because of concomitant profound immunosuppression and regimen-related cytopenias. This section will focus on the noninfectious complications of individual organs specifically attributable to conditioning toxicity. Opportunistic infection or, after allografting, GVHD must strongly be considered as etiologies for
organ dysfunction in the differential diagnosis of RRT. These alternative diagnoses are covered elsewhere under the appropriate subsection.

**Skin**

Generalized skin erythema is common after doses of TBI exceeding 12 Gy, but is self-limiting and rarely associated with skin breakdown. Regimens that contain cytosine arabinoside (Ara-C), thiotepa, busulfan, treosulfan, fludarabine, etoposide, and carmustine may also cause erythema. Hyperpigmentation typically follows the inflammatory dermatitis, with skin folds often being particularly noticeable. Skin biopsies during the first 3 weeks after transplant often show nonspecific inflammatory changes irrespective of cause, making them frequently unhelpful in distinguishing between RRT, drug allergies, or acute GVHD [24].

**Gastrointestinal Tract**

**Mucositis.** Most patients who receive high-dose conditioning regimens develop mucositis. Symptoms include inflammation, desquamation, and edema of the oral and pharyngeal epithelial tissue that typically presents within the first several days after HCT and usually resolves by the 3rd week. Anorexia, nausea, or other intestinal symptoms that persist after day 21 are more likely to be caused by GVHD or infection. Severe mucositis places patients at risk for aspiration and, occasionally, airway compromise, indicating the need for endotracheal intubation. Damage to the mucosa of the lower GI tract results in secretory diarrhea, cramping abdominal pain, and anorexia, and it facilitates translocation of intestinal bacteria with sepsis [23,25].

Mucositis is treated supportively with total parenteral nutrition, administration of intravenous fluids, and intravenous narcotics for pain control. It is important to recognize an iatrogenic narcotic bowel syndrome, characterized by abdominal pain and bowel dilatation, which occasionally may be a side effect of efforts to control painful symptoms of mucositis or SOS [26].

**Acute Upper Esophageal Bleeding.** The combination of mucositis, thrombocytopenia, and severe retching may result in a Mallory–Weiss tear, or esophageal hematoma [27]. The latter condition may have associated symptoms of dysphagia and retrosternal pain, and can be diagnosed by computed tomography (CT) scan. These conditions are treated supportively with transfusions to maintain platelet counts of greater than 50,000 per µL and optimal management of nausea and vomiting.
Liver

**Sinusoidal Obstruction Syndrome.** SOS (formerly referred to as veno-occlusive disease) develops in 10% to 60% of patients and is a clinical diagnosis based on the triad of tender hepatomegaly, jaundice, and unexplained weight gain usually within 30 days after HCT and in the absence of other explanations for these symptoms and signs [28–31]. It is more likely to be severe in patients with cirrhosis or fibrosis of the liver, or those with a history of hepatitis or liver irradiation (greater than 12 Gy), or chemotherapy-induced SOS [29,32].

Elevations of total serum bilirubin and serum transaminases are sensitive but nonspecific markers for SOS, and urinary sodium levels are typically low. A hepatobiliary ultrasound may show hepatomegaly, ascites, and dilatation of the hepatic vein or biliary system [33]. Doppler ultrasonography may show attenuation, or diagnostic, reversal of hepatic venous flow, but absence of this pattern does not exclude SOS [34]. If the diagnosis remains unclear, a transvenous liver biopsy may be helpful, and simultaneous measurement of hepatic venous pressure showing a gradient of greater than 10 mm Hg is highly specific for SOS [35].

Other causes of jaundice after HCT seldom lead to renal sodium avidity, rapid weight gain, or hepatomegaly [36]. Cyclosporine, methotrexate, and total parenteral nutrition are iatrogenic causes of hyperbilirubinemia, although rarely cause levels greater than 4 mg per dL [37]. Combinations of illnesses that may mimic SOS are cholangitis lenta (cholestatic effects of endotoxin [38], especially when combined with renal insufficiency), cholestatic liver disease with hemolysis and congestive heart failure, GVHD, and sepsis syndrome.

Once SOS is established, mathematical models can be used to predict prognosis, based on rates of increase in serum bilirubin and weight according to the elapsed time after transplantation [29,39]. The treatment for the 70% to 85% of patients who are predicted to have a mild or moderate course is largely supportive, with attention to management of sodium and water balance to avoid fluid overload [29,40]. Diuretics must be used judiciously to avoid depletion of intravascular volume and renal hypoperfusion. Paracentesis is indicated if the degree of ascites threatens respiratory function. There is no universally effective therapy for severe SOS. Defibrotide is a promising agent that has been shown to reverse SOS in some studies; however, it must be used with caution in patients with low platelet counts or other conditions that predispose to hemorrhage [30,41]. There is no support for insertion of peritoneovenous shunts and limited support for use of portosystemic shunts to reduce ascites [42]. Liver transplantation has
been successful in a small number of patients [43].

**Lung**

Pulmonary complications occur in 40% to 60% of patients after HCT [44,45]. Noninfectious pulmonary problems that may occur within 30 days from the transplant include idiopathic pneumonia syndrome (IPS), diffuse alveolar hemorrhage, pulmonary edema [46] due to excessive sodium and fluid administration or associated with SOS, or acute cardiomyopathy induced by cyclophosphamide, and sepsis with acute respiratory distress syndrome (ARDS) [47]. These complications occur more frequently in older patients, those who receive higher-dose conditioning regimens, and those with allogeneic donors, particularly HLA-disparate donors. Although the incidence of life-threatening pulmonary infections has decreased over the past decade owing to the introduction of routine antimicrobial prophylaxis, pulmonary complications continue to be a leading cause of death.

**Idiopathic Pneumonia Syndrome.** IPS is defined as a noninfectious inflammatory lung process that may be triggered by TBI and chemotherapies such as carmustine or busulfan. IPS has been reported in 5% to 10% of patients and occurs with a median onset of 2 to 3 weeks after myeloablative HCT [48,49]. Contributing factors to IPS lung injury may be release of inflammatory cytokines due to alloreactivity or sepsis. The clinical symptoms cannot be distinguished from infection and may include fever, nonproductive cough, and tachypnea. Hemoptysis is infrequent and more likely related to invasive fungal disease or diffuse alveolar hemorrhage. Radiographic imaging shows diffuse interstitial or multifocal intra-alveolar infiltrates. Arterial blood gases show hypoxemia and the alveolar–arterial oxygen gradient is increased. In the occasional patient who is not too ill to attempt lung function studies, a new restrictive pattern or a reduced diffusing capacity is characteristic. Measurements of pulmonary artery occlusion pressure or echocardiography may be useful to rule out cardiogenic pulmonary edema. Bronchoalveolar lavage or lung biopsy is necessary to exclude bacterial, fungal, or viral infection because *IPS is a diagnosis of exclusion* [50]. Multifocal bronchiolitis obliterans with organizing pneumonia (BOOP), also known as cryptogenic organizing pneumonia, may mimic late-onset IPS and has been more commonly associated with chronic GVHD [51].

Management of IPS is mainly supportive, including judicious diuresis to decrease pulmonary edema, transfusions of blood components to reverse bleeding diathesis, support of oxygenation, and administration of antibiotics to prevent superinfection with mold and bacteria, particularly in patients receiving high-dose glucocorticoids. Effective therapy for
idiopathic pneumonia has not been demonstrated. High-dose glucocorticoids (1 to 2 mg per kg) have been reported to have an adjunctive role in treatment of diffuse alveolar hemorrhage or idiopathic pneumonia \([52,53]\). Several studies have shown promising results for soluble tumor necrosis factor receptor (etanercept) used with or without glucocorticoids that resulted in an encouraging day-28 survival rate of 73\% \([53,54]\). Historically, IPS has been associated with a mortality rate of 50\% to 70\% \([49,55]\). Aggressive management, including initiation of mechanical ventilation to identify and treat reversible causes of respiratory failure, is a reasonable approach for most HCT recipients with diffuse or multifocal pulmonary infiltrates. When hemodynamic instability or sustained hepatic and renal failure develop, survival is extremely unlikely.

**Diffuse Alveolar Hemorrhage.** DAH may be a manifestation of diffuse alveolar damage. However, the erosion of blood vessels by fungal organisms always needs to be considered \([56]\). Hemorrhage occurs more frequently in older patients and those with malignancy, severe mucositis, or renal failure \([57]\). Symptoms and radiographic findings are similar to IPS, and hemoptysis is uncommon. Bronchoalveolar lavage should be performed early to evaluate for concomitant infection, which may be detected in about one-third of patients with DAH \([58]\). Bloody bronchoalveolar lavage (BAL) fluid with hemosiderin-laden macrophages is characteristic of diffuse alveolar hemorrhage. The treatment is largely supportive, including platelet transfusions and correction of coagulopathies with plasma or cryoprecipitate; however, several studies have also suggested a role for both corticosteroids and soluble tumor necrosis factor receptor \([54,59]\).

**Acute Respiratory Distress Syndrome.** Sepsis is a common cause of ARDS; however, an ARDS-like syndrome has also been described as a presenting feature of acute GVHD, typically early-onset (hyperacute) GVHD. ARDS has an extremely high mortality rate in the transplant population; recovery depends on aggressive treatment of associated infections and support of respiratory and cardiac function \([60]\). The diagnosis of ARDS is often complicated by the presence of other illnesses, such as SOS, hemorrhage, or disseminated intravascular hemolysis, which can cause difficulties with fluid management for which pulmonary artery catheterization can be helpful.
Cardiac complications occur in 5% to 10% of patients after HCT, but death from cardiac failure is uncommon [61,62]. Cardiac injury with hemorrhagic myocardial necrosis is a rare but known adverse effect of high-dose cyclophosphamide, one of the most commonly used chemotherapy agents in conditioning regimens. Risk factors for cyclophosphamide cardiotoxicity include the use of doses equal to or greater than 120 mg per kg, an underlying diagnosis of lymphoma, prior radiation to the mediastinum or left chest wall, older age, and prior abnormally low cardiac ejection fraction [62,63]. Patients who had prior cumulative anthracycline exposures of 550 mg per m² doxorubicin equivalents are at an increased risk for developing heart failure. Signs and symptoms of congestive heart failure may occur within a few days of receiving cyclophosphamide, whereas anthracycline-related cardiomyopathy may have a delayed onset. The electrocardiogram (ECG) may show voltage loss or arrhythmia, and echocardiography may reveal systolic dysfunction, pericardial effusion, or tamponade. Management includes attention to fluid and sodium balance, afterload reduction, and inotropes.

Pulmonary hypertension is an uncommon but serious complication of HCT that may lead to right ventricular failure [64]. It may be caused by pulmonary veno-occlusive disease (PVOD), as well as other more typical causes of increased pulmonary artery pressure. The diagnosis is made by cardiac catheterization. Pulmonary biopsy may be helpful in differentiating PVOD from other causes.

Kidney and Bladder

Acute Renal Failure. Acute renal failure (ARF), defined by doubling of baseline serum creatinine, occurs in 30% to 50% of all patients during the first 100 days after HCT, and most often during the first 10 to 30 days [65,66]. Occasionally, ARF develops during conditioning or infusion of HSC, as a consequence of tumor or red-cell lysis. ARF occurs frequently in the setting of SOS and is characterized by low urinary sodium concentration and high blood urea nitrogen–to–creatinine ratio, similar to the hepato-renal syndrome. Renal hypoperfusion, caused by acute hemorrhage, sepsis, or high-volume diarrhea, may result in ARF. Nephrotoxic drugs such as cyclosporine, tacrolimus, all amphotericin products, and aminoglycosides also should be considered as potential causes of ARF.

Thrombotic microangiopathy (TMA), endothelial damage caused by chemoradiotherapy, cyclosporine, tacrolimus, or sirolimus occurs in 5% to 20% of patients, more frequently in allograft recipients [65–68]. The hallmark of TMA is RBC fragmentation (schistocytes) associated with increased RBC turnover (increased reticulocytes; elevations of serum
lactate dehydrogenase and indirect bilirubin) without evidence for immune-mediated hemolysis or DIC. The syndrome ranges from subclinical hemolysis to a life-threatening hemolytic syndrome, the latter, being seen more frequently when sirolimus therapy is combined with cyclosporine or tacrolimus (calcineurin inhibitors [CNIs]) and immediately following conditioning with busulfan and cyclophosphamide. High-therapeutic or supratherapeutic serum levels of CNIs or sirolimus are more prone to be associated with TMA [69]. Management involves careful assessment of volume status and discontinuation or adjustment of the drug levels of the offending agent(s). There have been no controlled trials of plasma exchange, and therefore its utility has not been established for correction of TMA in the post-HCT setting [70]. Several other agents, including eculizumab and defibrotide, have been effective in limited numbers of patients [71].

**Hypertension.** Hypertension develops in approximately 60% of patients after HCT, more often in patients given CNIs for GVHD prophylaxis. Glucocorticoid therapy also contributes to the development of hypertension. Uncontrolled hypertension may lead to fatal intracerebral bleeding in thrombocytopenic patients. Therefore, hypertension should be anticipated and controlled medically. Most patients respond to conventional antihypertensive therapy, such as a calcium-channel blocker, angiotensin-converting enzyme inhibitor, or β-blocker. Correction of hypomagnesemia, which often confounds CNI therapy, may improve control of hypertension [72].

**Hemorrhagic Cystitis.** High-dose cyclophosphamide is commonly used for conditioning, and one of its toxic metabolites, acrolein, accumulates in the urine and may cause a hemorrhagic chemical cystitis during the conditioning regimen or later after HCT [73]. Measures to prevent hemorrhagic cystitis include aggressive fluid hydration to increase urine volume that dilutes and minimizes contact of acrolein with the mucosa, and administration of the drug mesna, which provides free thiol groups to detoxify acrolein. Viral infections, particularly adenovirus and BK virus, have also been implicated in the development of hemorrhagic cystitis, and the diagnosis is established by viral culture or polymerase chain reaction (PCR) test of a urine sample [74,75]. Unless there is evidence of disseminated infection, viral cystitis is managed with supportive therapy, including hydration and platelet transfusions. Severe hemorrhagic cystitis caused by adenovirus or BK virus that proves refractory to supportive therapy may respond to therapy with cidofovir [76].

**Central Nervous System**
Noninfectious complications include cerebrovascular events and encephalopathies due to metabolic, toxic, and immune-mediated causes. Focal symptoms are more indicative of infectious or cerebrovascular mechanisms, whereas diffuse symptoms such as delirium or coma may have metabolic causes. Fever is not necessarily associated with central nervous system (CNS) infections. Infection should be considered as the cause of any neurologic symptom and should prompt evaluation, including obtaining CT or magnetic resonance imaging (MRI) scans of the head and a sample of cerebrospinal fluid for appropriate cultures, cytochemistry stains, and PCR tests should be undertaken.

**Cerebrovascular Events.** Thrombocytopenia poses a risk for intracranial hemorrhage, which usually presents as abrupt onset of focal neurologic deficit or mental status changes [77]. Patients with sickle cell disease have a predisposition to CNS hemorrhage after HCT and should be managed carefully by ensuring sufficient platelet and magnesium levels and strict control of hypertension [78]. Ischemic stroke is an unusual complication after HCT, but has been reported in patients with *Aspergillus* infections, hypercoagulable states, or TMA [79].

**Toxic Encephalopathies.** Several agents used in conditioning regimens may cause encephalopathy, including high-dose busulfan and high-dose cytarabine. Seizure prophylaxis with Keppra, Ativan, or phenytoin should be considered during conditioning with high-dose busulfan or carmustine, particularly for young children. High-dose cyclophosphamide can be associated with the syndrome of inappropriate antidiuretic hormone (SIADH), rarely causing acute decline in the serum sodium that may prompt seizures. A rare syndrome of encephalopathy and hyperammonemia without other chemical evidence of liver failure has been reported after HCT [80]. Contributing factors may include hypercatabolism induced by conditioning, glucocorticoids, or sepsis, and high nitrogen loads associated with parenteral nutrition or intestinal hemorrhage. The syndrome is difficult to reverse and has a high mortality rate. Treatment involves hemodialysis and administration of ammonia-trapping agents, such as sodium benzoate or sodium phenylacetate. Metabolic encephalopathy may also be associated with gram-negative sepsis, hypoxic encephalopathy with IPS, and hepatic encephalopathy due to SOS or GVHD. Glucocorticoid therapy may be associated with psychosis, mania, or delirium in a dose-dependent fashion. Seizures or altered sensorium may be associated with the use of sedative-hypnotic drugs and have been reported as adverse side effects of many of the commonly used antibiotics and antiviral agents. Treatment of metabolic encephalopathies should be directed at the underlying problem and discontinuation of any offending drugs.
Related to a tendency to accumulate in nervous tissues owing to their lipophilic characteristics, CNIs can cause a range of neurologic toxicities including tremor, neuropathic pain, seizures, headaches, or visual disturbances [81]. Seizures should be managed with anticonvulsant therapy and cessation of the drug. When CNIs are essential for management of GVHD, substitution of one agent for the other, or reinstatement of the offending agent at a lower dose, may be feasible [82].

A unique and usually reversible syndrome of cortical blindness has been reported as a complication of cyclosporine treatment; hypertension and hypomagnesemia are thought to be predisposing factors [83]. Toxicity due to calcineurin inhibitor therapy may occur with “therapeutic” drug levels, and clinical suspicion is often confirmed by MRI scans that show multifocal areas of signal hyperintensity on T2 (time for 63% of transverse relaxation) and fluid-attenuated inversion recovery (FLAIR) sequences, most often in the occipital lobe white matter.

Hemolysis

RBC hemolysis may be encountered after HCT and may include more than one etiology. TMA may present as mild hemolysis or as a more severe form, as described previously [84,85]. Hemolysis mediated by major or minor blood group incompatibilities is only seen in recipients of allografts. Major ABO incompatibility occurs in 30% of allograft recipients and is defined by the presence of isohemagglutinins within recipient plasma that are directed against donor A or B antigens [86]. Minor ABO incompatibility also occurs in 30% of recipients and is defined by presence of isohemagglutinins within the donor plasma directed against recipient A or B. Bidirectional ABO incompatibility may be present as in the case of a type A recipient and type B donor or vice versa. After successful donor engraftment, the conversion of recipient to donor blood type may take weeks to months because of the relatively long half-life of RBCs.

Major ABO incompatibility poses a serious risk of severe hemolytic reactions at the time of infusion of the HSC product if preventative steps are not taken [87]. Immediate hemolytic reactions are more likely in the presence of high-level isoagglutinin titers. Therefore, RBCs are most commonly removed from the graft before infusion to avoid life-threatening hemolysis. Delayed recovery of donor hematopoiesis or hemolysis may occur because recipient plasma cells continue to produce isohemagglutinins for up to several months after HCT [86]. In this case, the diagnosis relies on detection of a positive direct antiglobulin test and the presence of isohemagglutinins directed against donor-type RBCs.
Management of major ABO incompatibility includes the transfusion of group O RBCs, donor-type platelets, and donor-type plasma until isohemagglutinins against donor-type RBCs disappear. In the rare cases of ongoing hemolysis due to persistence of donor-directed isohemagglutinins, additional therapy with immunosuppressive agents, erythropoietin, plasma exchange, anti-B-cell antibodies (rituximab), or plasma exchange may be considered [88].

Minor ABO incompatibility poses a risk for mild and self-limited hemolysis at the time of infusion [87]. Delayed hemolysis, seen more commonly after PBSC transplantation, is mediated by clonally expanded donor “passenger lymphocytes” and can present as an abrupt and potentially fatal hemolytic transfusion reaction typically at 1 to 2 weeks after HCT [86,89]. In contrast to major ABO incompatibility, pretransplant donor isohemagglutinin titers do not predict the severity of hemolysis following minor ABO-mismatched HCT. The diagnosis relies again on the detection of a positive direct antiglobulin test and the presence of isohemagglutinins directed against recipient-type RBCs. To prevent hemolysis, plasma should be removed from the donor HSC product if donor hemagglutinin titers are high. Emergence of donor-derived RBC and isohemagglutinin titers should be monitored after allogeneic HCT. Management of minor ABO incompatibility after HCT includes supportive care with judicious fluid management aimed at preventing ARF, and the transfusion of group O RBCs and recipient-type platelets and plasma. There is no convincing evidence to support the use of plasma exchange.

**Infection**

Conditioning regimens and GVHD severely impair host defense mechanisms, and the process of immune reconstitution necessarily requires many months for completion. Together, these factors place patients at high risk for acquisition of severe infections. Proper medical care of patients after HCT includes measures to monitor and prevent infection, as it is a leading cause of death.

Prevention of infection is of vital importance to the success of HCT procedures. Hospitalized patients should be housed in single rooms that have positive-pressure air flow and ventilation systems with rapid air exchange and high-efficiency particulate air filtration [90]. Strict visitation, hand washing, and isolation policies should be instituted to prevent introduction or spread of communicable disease. A daily program of skin and oral care should include bathing all skin surfaces with mild soap, brushing teeth with a soft brush, frequent rinsing of the oral cavity with saline, and good perineal hygiene. The diet should exclude foods known to contain bacteria or fungi, and patients should avoid exposure to
dried or fresh plants or flowers. Caregivers should be trained in the proper handling of central venous catheters.

Immunologic reconstitution after HCT can broadly be categorized into three phases, which are characterized by a spectrum of opportunistic infections. Recommendations for antimicrobial prevention of opportunistic infections after HCT are outlined in Table 64.2.

Recommendations are: “A,” should always be offered; “B,” should generally be offered; “C,” optional; “D,” should generally not be offered. Evidence is “level I” if it is derived from ≥1 properly designed randomized, controlled trial, “level II” if it is derived from ≥1 well-designed clinical trial without randomization, from cohort or case-controlled analytical studies, or from multiple time series or dramatic results from uncontrolled experiments, and “level III” if it is derived from opinions of respected authorities based on clinical experience. Qualifiers, “a,” indicates that evidence is directly from study(s) in GVHD, or “b” if the evidence was derived indirectly from study(s) in analogous or other pertinent disease.

ANC, absolute neutrophil count; CMV, cytomegalovirus; DS, double strength; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; HSV, herpes simplex virus; IgG, immunoglobulin G; IV, intravenous; max, maximum dose; MTX, methotrexate; PJP, Pneumocystis jiroveci pneumonia; PCR, polymerase chain reaction; SMX, sulfamethoxazole; TMP, trimethoprim; VK, V potassium; VZV, varicella zoster virus.

**Before Engraftment Period**

The period before engraftment (less than 30 days posttransplant) is characterized by neutropenia and oral and gastrointestinal mucosal damage. The most common infections are bacterial and fungal. The use of indwelling central venous catheters heightens the risk of blood infections with organisms that colonize the skin, such as coagulase-negative *Staphylococcus* or *Candida* spp., and gastrointestinal mucosal damage increases the risk of infections with enteric organisms, such as
Escherichia coli. Clostridium difficile toxic colitis can be a common infection in transplant patients, particularly those patients in intensive care units. Patients with a history of prolonged neutropenia before HCT are at risk for developing fungal infections involving the skin, lung, and sinuses, which are typically a mold such as Aspergillus, or the liver and spleen, typically Candida spp. The most likely viral infection in this period is herpes simplex virus. Fever of unknown origin also occurs commonly during the neutropenic period. Prophylactic systemic antibiotics are conventionally administered to reduce the risk of bacteremia during the neutropenic period, although improvement in survival has not been demonstrated [90]. Administration of growth factors, such as granulocyte colony-stimulating factor, shortens the duration of neutropenia, but there is little evidence for improvement in outcome after allogeneic HCT.

Following Engraftment Period

The period following engraftment (30 to 100 days posttransplant) of allogeneic HSC is characterized by skin and mucosal damage and compromised cellular immunity related to GVHD and its treatment. Viral (CMV) and fungal (Aspergillus, Pneumocystis jiroveci) infections predominate during this period. Gram-negative bacteremias related to GVHD-associated mucosal damage and gram-positive infections due to indwelling catheters remain a risk. Other causes of fever of unknown origin after engraftment include occult sinusitis, hepatosplenic candidiasis, and pulmonary or disseminated Aspergillus infection.

Late Phase

The late phase (greater than 100 days posttransplant) after allogeneic HCT is characterized by a persistently impaired cellular immunity in patients with chronic GVHD. Patients with chronic GVHD are highly susceptible to recurrent bacterial infections, especially from encapsulated bacteria, including Streptococcus pneumonia, Hemophilus influenzae, and Neisseria meningitides (functional asplenia). Bronchopulmonary infections, septicemia, and ear, nose, and throat infections occur. Common nonbacterial infections at this time include varicella zoster, CMV, Pneumocystis jiroveci, and Aspergillus.

Evaluation and Treatment
Signs and symptoms of infection may be diminished in patients who are neutropenic or receiving immunosuppressive drugs. Thus, preemptive antibiotic therapy should be instituted promptly for any fever during the neutropenic period because infections can progress rapidly to a fatal outcome [90]. The febrile patient should be examined thoroughly for source of infection, including the oral cavity, perianal tissue, and skin surrounding the central venous catheter. Cultures should be obtained of blood, urine, and stool if diarrhea is present; and chest radiograph should be performed. Antibiotic therapy should provide empiric coverage for the most common organisms, gram-positive bacteria that colonize the skin and oral cavity, as well as the less common but more virulent gram-negative bacteria that arise from the GI tract. Broad-spectrum antibiotic therapy should be continued through the duration of neutropenia, even if fever resolves. If fever persists, the antibiotic regimen should be broadened after 4 days to provide empiric treatment of fungi. *C. difficile* infection should be considered in patients with diarrhea and can be treated with oral metronidazole or oral vancomycin.

Evaluation of persistent fevers after granulocyte recovery should consider occult sources of bacterial infection, such as sinuses, perirectal tissue, or central venous lines, as well as viral or fungal etiologies. Removal of the central venous catheter is occasionally required. Viral infections must be considered in patients with GI symptoms and may involve the esophagus, upper and lower intestines, or liver [91]. The diagnosis is established by biopsy or brushings taken from the center of the lesions so as to include infected endothelial cells and submucosal tissue. Patients with active chronic GVHD should receive prophylaxis for *P. jiroveci* pneumonia (PJP) with trimethoprim-sulfamethoxazole and for encapsulated organisms with daily trimethoprim-sulfamethoxazole, penicillin, or azithromycin.

Infectious causes of pulmonary infiltrates must be differentiated from noninfectious causes to ensure prompt institution of appropriate therapy [55]. BAL should be performed without delay to establish the etiology of diffuse infiltrates, unless clearly related to pulmonary edema [92,93]. BAL specimens should be assayed for the presence of common nosocomial bacteria as well as *Legionella, Mycobacteria*, and *Nocardia*; *P. jiroveci*; fungi other than PJP; respiratory viruses; and herpes group viruses by cultures and immunocytochemical stains. Focal pulmonary infiltrates that occur after HCT are most frequently caused by infection, particularly fungal infection [92,93]. Evaluation of a focal infiltrate should include a CT scan to delineate the number and extent of infiltrates. BAL should be performed as a first step because the procedure is minimally invasive and historically has produced a diagnosis in 50% of patients with fungal lesions using standard diagnostic approaches, although the predictive value of negative results was poor [94]. The
increasing use of more sensitive diagnostic approaches like galactomannan antigen testing \[95\] or molecular methods to detect fungi or viral pathogens continues to improve the yield of BAL \[96,97\]. Transbronchial biopsy is not recommended because it has not been shown to improve sensitivity in these situations, and often thrombocytopenia precludes the ability to perform the procedure safely. Percutaneous fine-needle aspiration is indicated for diagnosis of peripheral infiltrates that cannot be evaluated by BAL. Fine-needle aspiration has a sensitivity of approximately 67\% for diagnosis of fungal infection, but it has a poor negative predictive value. If the diagnosis is not ascertained after BAL or fine-needle aspiration, a biopsy is required \[98\]. Specimens should be evaluated histologically and undergo testing for bacteria, fungi, and viruses by appropriate cultures and immunocytochemical stains as noted previously. Surgical resection of a solitary fungal lesion may improve the chances for cure \[99\].

**Opportunistic Infections**

**Pneumocystis jiroveci Pneumonia.** Inadequate cell-mediated immunity poses a risk for development of PJP infection after HCT \[100\]. Recommendations for prevention of PJP are found in Table 64.2 \[90\].

**Fungal Infections**

Factors that predispose to invasive yeast infections include neutropenia, mucosal barrier disruption, and broad-spectrum antibiotics that promote colonization of the GI mucosa \[101\]. Candidal infections generally occur within the first 3 weeks after HCT, coinciding with the period of neutropenia, although a second period of risk occurs during treatment for chronic GVHD. Invasive candidiasis may involve the liver and spleen, with potential for dissemination to kidneys or rarely, the CNS \[102\]. The diagnosis of invasive candidiasis is difficult because blood cultures are negative in approximately one-half of the cases with organ involvement. Recommendations for prevention of candidiasis are found in Table 64.2 \[90,103\]. Fluconazole is effective for treatment of the most common *Candida* spp., *C. albicans* and *C. tropicalis* \[104,105\] (see Table 64.2), but does not prevent or treat infection with *C. glabrata*, *C. krusei*, or *C. parapsilosis*. Lipid-complexed amphotericin products, echinocandins, or other azoles may be useful alternatives \[106\]. Removal of the central venous catheter should be considered when *Candida* sp. is isolated from blood cultures. Because fungal vegetations on heart valves may occur, echocardiography should be considered to evaluate for this.

Although the era of improved fungal prophylaxis has reduced the incidence of invasive mold infections after HCT to <5\% among affected
patients, the mortality remains high [107]. The incidence of Aspergillus infections is highest within the first month after HCT, and there is a second peak incidence during chronic GVHD. Aspergillus infections have been difficult to diagnose by standard methods, and more than 20% of the cases have been diagnosed only at autopsy. Cultures of BAL fluid are negative in 50% of pulmonary disease; therefore, the diagnosis frequently requires a biopsy of affected tissues [108]. The Aspergillus Galactomannan Enzyme Immunoassay detects a polysaccharide secreted from Aspergillus hyphae and is a useful screening tool, with a sensitivity of 65% and specificity of 95% [109]. High-risk patients, those with severe GVHD treated with high-dose corticosteroids, should be given prophylaxis with agents like voriconazole or posaconazole, which is active against aspergillosis and certain other molds. Because invasive aspergillosis is associated with a high mortality rate, documented or suspected infections should be treated aggressively with voriconazole or another mold-activeazole, lipid-complexed amphotericin products, or combination therapy [110]. Surgical removal of infected tissue should be restricted to cases of circumscribed disease [111].

Viral Infections

Cytomegalovirus. Protection from exposure by use of seronegative or leukocyte-reduced blood components has reduced the incidence of CMV infection among seronegative patients, whereas ganciclovir has been shown to be an effective agent for prevention of CMV disease in seropositive patients (see Table 64.2). Two approaches have proven successful for reducing the incidence of CMV disease post HCT: (1) ganciclovir prophylaxis initiated after engraftment, with careful monitoring of the patient for marrow suppression, or (2) weekly monitoring for CMV reactivation with serum PCR assays, followed by prompt institution of ganciclovir when the CMV copy number reaches a positive threshold [112]. Generally, surveillance CMV PCR testing is performed weekly from transplant day 0 through day 100; however, monitoring generally is continued for CMV-positive patients on high-dose corticosteroids.

Although prophylaxis greatly reduces the risk for CMV disease, severe pneumonitis, gastroenteritis, hepatitis, or bone marrow failure continue to occur in a small proportion of patients [113]. The diagnosis of CMV pneumonitis can be established in most patients by PCR assay or rapid shell vial culture of BAL fluid [50]. CMV enteritis is often indistinguishable from GVHD clinically, and the diagnosis relies on
endoscopic evaluation [114]. CMV enteritis appears as ulcerations of the esophagus, stomach, or intestines. Viral cultures and histologic stains of the affected tissue are used to establish the diagnosis. Treatment of CMV infection includes ganciclovir (foscarnet or cidofovir are acceptable alternatives) in combination with immune globulin [115–117]. Foscarnet can be used in place of ganciclovir if significant marrow toxicity occurs or drug resistance is identified.

**Herpes Simplex Virus.** Herpes simplex virus (HSV) is the most common cause of infectious mucositis after HCT and may cause life-threatening encephalitis, hepatitis, or pneumonia in immunocompromised patients [118]. HSV pneumonitis or hepatitis is associated with high mortality rates; although less serious, HSV mucositis produces severe local pain and swelling. Acyclovir prophylaxis has been shown to be very effective for prevention of HSV reactivation in seropositive patients and for treatment of established disease [117,119] (see Table 64.2).

**Varicella Zoster Virus.** Varicella zoster virus (VZV) causes life-threatening disease in immunocompromised patients as a primary infection or reactivation of endogenous virus. Exposed seronegative patients should receive VZV immune globulin within 96 hours if available, and acyclovir should be administered from days 3 to 22 after exposure [120]. Among seropositive patients, VZV reactivation occurs in approximately 40%, with the highest incidence around 5 months after HCT [121]. Prophylaxis with acyclovir is recommended for seropositive patients until 1 year after HCT or until complete discontinuation of immunosuppressive therapy for chronic GVHD immunity [117,122,123] (see Table 64.2). VZV infection typically causes local skin involvement, but it can disseminate in immunocompromised patients, resulting in pneumonitis, esophagitis, pancreatitis, hepatitis, or encephalitis [124–126]. VZV hepatitis may present as a syndrome of fever, severe abdominal pain, and elevated aminotransferase levels, and because it is associated with a high mortality rate, it should be treated presumptively with high-dose acyclovir [36,117]. For localized infection, a short course of intravenous acyclovir for 24 to 48 hours can be followed by oral valacyclovir for the duration of therapy.

**Respiratory Viruses.** Respiratory viruses may spread quickly within HCT patient populations, causing epidemics of life-threatening infection. Respiratory syncytial virus (RSV), influenza, and parainfluenza are the most frequently encountered respiratory viruses in these situations
Symptoms of upper respiratory infection should prompt cultures of nasopharyngeal secretions, careful monitoring for progression of disease, and isolation to prevent spread to other patients. Patients in the period before engraftment are at greatest risk for progression to lower-tract disease with RSV. Once lower-tract disease occurs, however, mortality is high regardless of engraftment status [129]. If lower-tract disease is suspected, BAL should be performed to obtain samples for viral fluorescence antibody and PCR tests and viral cultures [93].

**Adenovirus.** Adenovirus and polyoma BK virus are common causes of hemorrhagic cystitis after HCT [130,131]. When disseminated, adenovirus can cause hemorrhagic enterocolitis, interstitial pneumonitis, myocarditis, nephritis, meningoencephalitis, or severe hepatitis. Adenoviral infections occur more commonly in children and after allogeneic grafts. Patients with poor T-cell function, such as recipients of T-cell–depleted grafts or those receiving intensive immune-suppressing therapies, are at greatest risk for disseminated infection. Disseminated infections are often difficult to detect by viral cultures, and PCR assays may be more useful [132]. The most promising treatment results have been reported after administration of cidofovir, although renal insufficiency is a potential side effect [133]. Polyoma BK virus should be considered in the differential diagnosis of renal insufficiency in patients on chronic immune suppression and can be diagnosed by renal biopsy.

**Epstein–Barr Virus.** Epstein–Barr virus (EBV) seropositive immunocompromised patients are at risk for development of life-threatening lymphoproliferative disease (LPD) after HCT [134,135]. The risk for EBV-LPD is highest among patients who receive T-cell–depleted grafts or who are given intensive immune suppression for treatment of GVHD. The diagnosis is made by biopsy of enlarged nodes or affected tissue. A presumptive diagnosis can be made in high-risk patients who have clinical symptoms and elevated plasma or cellular EBV DNA copy number [136]. The mainstay of therapy is reduction or elimination of immunosuppressive therapy to allow reconstitution of EBV-specific T-cell immunity [117]. However, it may not be feasible to eliminate immunosuppression therapy without risking a flare of life-threatening GVHD. Some studies have shown encouraging results with mAb directed against CD20, which targets EBV-infected B cells [137]. EBV-LPD that develops in recipients of T-cell–depleted grafts may be ameliorated by infusion of donor T lymphocytes [138].

**Graft Rejection**

Graft rejection presents as failure to recover hematopoiesis after transplantation, termed *primary graft failure*, or as the loss of an
established donor graft, termed *secondary graft failure*. Persistence of neutropenia (an absolute neutrophil count of more than 100 cells per µL) after day 26 is associated with increased risk of early mortality [139]. Although the molecular and cellular mechanisms are not completely understood, graft rejection appears to be mediated preferentially by recipient T cells [140]. Natural killer cells and host allo-antibodies also have been implicated in graft rejection. Graft rejection is more common after RIC or after transplant of T-cell–depleted grafts, UCB grafts, and grafts containing insufficient numbers of HSC.

Quantitation of donor engraftment (donor chimerism), using PCR-based techniques to detect donor-specific variable nucleotide tandem repeats (VNTR) sequences, may be helpful in determining whether the graft has been rejected, in which case the peripheral blood T cells will be primarily of host origin, or whether the donor graft is not functioning, in which case the cells will be of donor origin. In the latter case, other causes of graft suppression should be considered, including relapse, medications such as ganciclovir or trimethoprim-sulfamethoxazole, mycophenolate mofetil, or viral infections such as CMV, human herpes virus 6, or parvovirus B19. In either case, graft failure after myeloablative conditioning is a life-threatening complication because autologous reconstitution is uncommon and results in death from hemorrhage or infection. A range of cellular therapies have been used to overcome rejection ranging from donor lymphocyte infusions in the case of declining donor T-cell chimerism, possibly combined with immunosuppressive therapy. In fulminant rejection, retransplantation is necessary, using the same or another donor. Preferentially, conditioning should differ from that used at the first transplant to avoid unnecessary toxicity, and a high graft cell dose is recommended.

**Graft-Versus-Host Disease**

The most significant immunological barrier to successful HCT is the graft-versus-host reaction that can result in life-threatening inflammation and tissue destruction. Donor T cells that recognize disparate recipient alloantigens are the central mediators of GVHD. The most important alloantigens are those encoded by the major histocompatibility complex, or HLA system, although non-HLA antigens may certainly be involved. Despite the significance of GVHD as a complication of HCT, patients who develop GVHD have lower relapse rates than do patients without GVHD, and this can also be explained by an immunologically mediated graft-versus-tumor effect that helps eradicate the underlying malignancy.

**Acute GVHD**
The incidence and severity of acute GVHD are determined primarily by the degree of HLA disparity and influenced by the nature of GVHD prophylaxis [13]. Severe acute GVHD (grades III to IV) develops in 15% of recipients transplanted from HLA-identical sibling donors and in a greater proportion of those given unrelated or mismatched grafts [141]. Acute GVHD typically begins abruptly at 2 to 4 weeks after myeloablative HCT and generally occurs before day 100, but the onset may be delayed after nonmyeloablative HCT. The clinicopathologic syndrome is consistent with various combinations of inflammatory dermatitis, enteritis, and hepatitis, which reflect the pathophysiology of T-cell activation with generation of cytotoxic lymphocytes and elaboration of inflammatory cytokines that cause tissue damage. The severity of acute GVHD in the three main target organs (skin, liver, and GI tract) is staged 1 through 4 on the basis of accepted criteria that primarily include the extent of rash, magnitude of hyperbilirubinemia, and volume of diarrhea. The various combinations of skin, liver, and GI involvement can then be used to assign an overall grade of GVHD: grade I being mild and grade IV being life threatening (Table 64.3) [142]. When cellular injury is severe, GVHD of the skin may manifest with bulla formation and skin ulceration. In the GI tract, symptoms range from mild anorexia, to nausea and vomiting, or to severe bloody diarrhea with cramping periumbilical pain.

**Chronic GVHD**
Chronic GVHD (CGVHD) occurs in approximately 30% to 60% of transplant recipients, more often when the donor is not an HLA-identical sibling and when there is a history of acute GVHD [143]. There is a higher risk for developing CGVHD with growth factor–mobilized PBSC grafts compared with marrow grafts [5,6]. CGVHD is also more likely when the recipient or donor is older or CMV seropositive, or in a male patient who receives HSC from a multiparous female donor. Risk factors for mortality at the time of diagnosis of CGVHD include platelet counts less than $100 \times 10^9$ per L, greater than 0.5 mg/kg/d prednisone, serum total bilirubin greater than 34 $\mu$mol per L, older recipient, prior acute GVHD, older donor, and graft-versus-host HLA mismatching.

CGVHD is defined without reference to time after HCT, but by the presence of hallmark CGVHD features, which resemble autoimmune diseases such as systemic sclerosis, Sjögren syndrome, primary biliary cirrhosis, wasting syndrome, bronchiolitis obliterans, immune cytopenias, and chronic immunodeficiency (Table 64.4) [144]. The overall severity of CGVHD is determined by a 0- to 3-point score (none, mild, moderate, severe) that reflects the clinical effect of CGVHD on the patient’s functional status in any number of different organs [145]. CGVHD frequently involves the skin, liver, eyes, mouth, upper respiratory tract, lungs, and esophagus. Less frequently, serosal surfaces, lower GI tract, female genitalia, or fascia are involved. Major causes of morbidity include scleroderma, contractures, ulceration, keratoconjunctivitis, strictures, obstructive pulmonary disease, and weight loss. Uncontrolled chronic GVHD interferes with immune reconstitution and is strongly associated with increased risks of opportunistic infections and death.

---

a Seen in chronic GVHD, but are insufficient alone to establish the diagnosis.
b Seen in both acute and chronic GVHD alone to establish a diagnosis of chronic GVHD.
In all cases must exclude infection, drug effects, malignancy, or other causes.

Diagnosis of chronic GVHD requires biopsy or radiology confirmation (or Schirmer test for eyes).

AIHA, autoimmune hemolytic anemia; ALT, alanine aminotransferase; AST, aspartate aminotransferase; COP, cryptogenic organizing pneumonia; GI, gastrointestinal; ITP, idiopathic (immune) thrombocytopenic purpura; PFTs, pulmonary function tests; ULN, upper limit of normal range for age.

Confirming the Diagnosis of GVHD

Unlike CGVHD, the clinical signs of acute GVHD are not considered sufficiently pathognomonic to establish the diagnosis, especially when there is isolated organ involvement. However, the combination of rash, nausea, and voluminous diarrhea, occurring at the time of, or early after, neutrophil engraftment makes the diagnosis very likely. The differential diagnosis involves ruling out other causes of rash, diarrhea, or liver toxicity as listed in Table 64.5. Tissue biopsies of the skin, liver, or stomach are recommended to confirm a histologic diagnosis of GVHD and, most importantly, to exclude opportunistic infection; however, the interpretation of biopsies performed within 3 weeks of myeloablative therapy may be problematic because it is difficult to separate cellular injury induced by chemoradiotherapy from GVHD. The gastric antral mucosa provides the most sensitive site for evaluation of intestinal GVHD and is preferred to duodenal biopsy because there is less risk for bleeding complications. The histologic hallmark of GVHD-induced cellular injury is apoptosis, observed in epidermal basal keratinocytes, bile duct, or intestinal crypt epithelial cells, and is often associated with infiltration by lymphocytes [146,147]. Biopsy is unnecessary to confirm the presence of chronic GVHD if at least one diagnostic feature is present, but histologic confirmation or other pertinent testing is necessary when CGVHD features are only distinctive or suggestive (see Table 64.4).

### Prevention of GVHD

GVHD prevention strategies are almost always incorporated into the overall treatment plan, and these include optimizing the choice of allogeneic donor and stem cell product based on known risk factors for GVHD, T-cell depletion of the donor HSC graft as discussed earlier, or, most commonly, posttransplant immunosuppression. Ursodeoxycholic acid should be given to all patients irrespective of the approach to GVHD prophylaxis because it improves liver function and reduces the incidence of hepatic GVHD [148].

**Postgrafting Immunosuppression.** In the absence of T-cell depletion, posttransplant immune suppression must be administered to control donor alloreactive T cells. Most GVHD prophylaxis regimens include a CNI (cyclosporine or tacrolimus) in combination with one or two additional agents, such as methotrexate, mycophenolate mofetil (MMF), or sirolimus [149–152]. In some settings, cyclophosphamide is given on days 3 and 4 after HCT, followed by prophylaxis with a CNI and MMF [15]. Steady-state serum CNI and sirolimus levels require monitoring. Dose reductions should be made when toxicities emerge or when serum trough levels exceed the upper limit of the therapeutic range.

### Treatment of GVHD

Despite GVHD prophylaxis regimens, 30% to 80% of allogeneic HCT
recipients develop acute GVHD and require additional therapy with glucocorticoids.

**Acute GVHD.** Glucocorticoids have been the mainstay of primary therapy for acute GVHD. Initial starting doses have been recently calibrated to the severity and extent of organ involvement as demonstrated by one large retrospective study [153]. For the one-third of patients who develop GVHD without liver involvement, and whose GI symptoms are defined as stage 1 (anorexia, nausea, or vomiting with peak stool volume less than 1,000 mL per day), with or without rash involving less than 50% of the body surface, treatment may reasonably begin at 1 mg/kg/d methylprednisolone (or oral equivalent) combined with topical and minimally absorbed glucocorticoids (beclomethasone and/or budesonide). When there is liver involvement, or when intestinal and skin GVHD is greater than defined above, methylprednisolone is typically begun at a dose of 2 mg/kg/d for up to 14 days [154]. Once the symptoms (rash, diarrhea, abdominal pain, and liver dysfunction) are controlled, a glucocorticoid taper should be instituted. For treatment of symptoms that do not respond to the initial treatment, there is no benefit for administration of doses greater than 2 mg/kg/d of methylprednisolone, and alternative approaches to steroid-refractory GVHD must be considered, as discussed below [155].

**Chronic GVHD.** In practice, systemic therapy is considered when chronic GVHD is present in more than two organs or when there are moderate to severe abnormalities of a single organ with functional impairment (Table 64.6). In contrast, systemic therapy is generally not warranted for patients with mild abnormalities of one or two organs that do not cause functional impairment. However, mild chronic GVHD does warrant systemic therapy when either thrombocytopenia or steroid treatment is present at diagnosis.

\(^d\) At least one site functionally impaired without major disability (Score 2 or 3) or more sites without clinically significant functional impairment (each with score \(\leq 1\)).
\(^e\) Major disability at any site (score 3, or score \(\geq 2\) in lung).

GVHD, graft-versus-host disease.

Standard primary therapy for clinical extensive CGVHD usually begins with glucocorticoids and extended administration of a CNI. After newly diagnosed CGVHD manifestations have been controlled by daily glucocorticoids, the judicious use of glucocorticoids at the lowest effective dose and alternate-day administration can minimize steroid-related side effects. The median duration of systemic immunosuppression for the treatment of CGVHD approximates 2 to 3 years [156,157]. Longer therapy tends to be required for recipients of PBSCs, male patients with female donors, multiple organ involvement at the onset of CGVHD, graft-versus-host HLA mismatch, and hyperbilirubinemia. Infection from a broad array of pathogens is a major cause of mortality among patients with CGVHD; therefore, antibiotic prophylaxis to prevent infection (Table 64.2) and supportive care to minimize morbidity and prevent disability are critically important components of CGVHD management [158,159].

**Steroid-Refractory GVHD.** Glucocorticoids often fail to control acute GVHD manifestations such that 40% to 60% of patients have steroid-refractory (SR) acute GVHD. SR-GVHD has been defined operationally as the progression of acute GVHD symptoms beyond 3 days after starting methylprednisolone. Persistence of GVHD beyond 7 to 14 days should also be considered failure of response. The prognosis of acute GVHD can be related to its overall severity (grade) and response to glucocorticoids [160]. Grade III and IV SR acute GVHD, especially with visceral involvement, requires urgent initiation of effective secondary therapy [154].
Unfortunately, there is no generally accepted therapy for SR acute GVHD. A full review of the various secondary GVHD therapies is beyond the scope of this review, but various approaches are listed in Table 64.7 [154]. Polyclonal antithymocyte globulins (ATG) or monoclonal antibodies are generally used to treat life-threatening visceral manifestations where urgent control of SR acute GVHD is necessary. Unfortunately, longer term survival has been unusual when visceral manifestations are severe because progressive organ dysfunction is often irreversible and because second-line therapies constitute a “second hit” to an immune system that has already been impaired by cumulative exposure to high-dose prednisone. In this regard, high daily prednisone doses increase the risk for CMV viremia and invasive aspergillosis [161,162].

| Therapy Options for Steroid-Refractory Acute Graft-versus-Host Disease |
|---------------------------------|------------------|
| **Therapy** | **Comments** |
| **Systemic** | |
| Polyclonal | |
| Antithymocyte globulin (ATGAM\(^a\), Thymoglobulin\(^b\)) | Delayed use appears to be very ineffective. Skin responds best |
| Monoclonal | |
| Anti-IL2 (daclizumab\(^c\), basilixumab\(^e\)) | Depletes conventional and regulatory T cells |
| Anti-TNF\(\alpha\) (infliximab\(^e\)) | Consider early for refractory lower GI tract |
| Anti-CD52 (alemtuzumab\(^c\)) | Depletes T & B cells (lower risk EBV PTLD) |
| Fusion proteins | |
| Anti-IL2 (denileukin diftitox) | Anti-T cell but also depletes regulatory T cells |
| Anti-TNF\(\alpha\) (etanercept) | TNF inhibitor |
| Macrolides and antimetabolites | |
| Tacrolimus | Inhibits conventional and regulatory T cells |
| Sirolimus | Inhibits conventional but not regulatory T cells |
| Mycophenolate mofetil | Enteric-coated formulation may minimize |
Pentostatin toxicity but liquid formulation not available

Universal lymphopenia and late infections were dose limiting. Best responses in skin

Extracorporeal photopheresis Mechanism includes facilitation of regulatory T cells; particularly effective in skin, infrequently associated with opportunistic infections

Mesenchymal stem cells Mechanism poorly understood but thought to modulate tissue repair

### Topical

| Glucocorticoids | Budesonide | Use as steroid-sparing agent in lower GI tract |
| Glucocorticoids | Beclomethasone<sup>d</sup> | Use as steroid-sparing agent in upper GI tract |
| PUVA | PUVA, psoralen and ultraviolet A. |

<sup>a</sup>Equine  
<sup>b</sup>Rabbit  
<sup>c</sup>Humanized  
<sup>d</sup>Not commercially available]  
<sup>e</sup>Chimeric murine-human

When CGVHD becomes refractory to steroids, in contrast to SR acute GVHD, secondary therapy generally avoids potent antibody therapies unless the manifestations overlap with the disease features typically associated with severe acute GVHD. The time to complete resolution of classical CGVHD manifestations is in the order of weeks to months, and total duration of therapy spans months to years. Therefore, secondary therapies for SR-CGVHD must try to avoid profound T-cell depletion and must generally be more easily delivered chronically in the outpatient setting. Ideally, second-line agents should promote transplantation tolerance so that the morbidity associated with prolonged use of glucocorticoids and other immunosuppressive agents can be minimized. Agents or strategies that have been used more recently to treat CGVHD, and particularly when fibrotic or sclerotic manifestations are present,
include sirolimus, extracorporeal photophoresis, rituximab, low-dose interleukin-2, and imatinib. A number of ancillary measures that are used with topical intent are often used to target specific organ involvement [158].

The goal of solid-organ transplantation is maximizing graft survival while minimizing the morbidity and mortality associated with the immunosuppressive regimen necessary to prevent rejection, infection, malignancy, and graft-versus-host disease (GvHD). Allograft rejection in transplant recipients is the feared outcome of the complex and intricate mammalian immune system.

The history of solid-organ transplantation has demonstrated that graft survival depends on successfully manipulating the immune system. However, any modification of the host’s defense mechanism can bring unwanted consequences, such as rejection, infection, malignancy, and GvHD. In the early days of solid-organ transplantation during the 1960s, it became clear that suppressing the immune system of the prospective host would be required for sustained graft function. Acute rejection (AR) and graft loss are now largely preventable and effectively treated complications of transplantation in contrast to the earliest experiences just over half a century ago.

Successful antirejection treatment and, more importantly, the ability to markedly reduce the incidence of rejection through preventive strategies with effective immunosuppressive agents has allowed solid-organ transplantation to become routine in clinical practice. Initially, successful allogeneic renal transplantation was achieved using a combination of a high-dose corticosteroid and azathioprine [1]. Contemporaneous
observations in the very first transplant recipients demonstrated that nonselective immunosuppressive therapy prolonged graft (and patient) survival but led to an increased susceptibility to infection, often with unusual, opportunistic pathogens [2]. Furthermore, immunosuppressed transplant recipients were noted to have an increased susceptibility to malignancy [3].

In the over 50 years since the report of the initial 12 recipients treated for rejection of allogeneic renal grafts, solid-organ transplantation has become mainstream. Kidney, liver, heart, and lung transplants are now standard-of-care therapies for end-stage renal, hepatic, cardiac, and pulmonary disease, respectively. Pancreas and pancreatic islet-cell transplants restore the β-cell function in patients with diabetes mellitus. The small bowel has also been successfully transplanted as a treatment for patients with short gut syndrome. Such strides have been made possible by the accumulated advances in critical care, organ procurement and preservation, surgical techniques, anesthesia management, tissue typing, immunosuppressive therapy, and the use of antibacterial, antifungal, and antiviral agents for both prophylaxis and treatment of posttransplant infection. Table 65.1 lists some of the major advances in the management of GvHD, infection, malignancy, and rejection in transplant recipients.

Yet even with the expanded immunosuppressive armamentarium of the 21st century, it remains difficult to finely balance the suppression of the host immune system (to allow acceptance and even tolerance of the graft) without oversuppressing immune function (and thereby leaving the host vulnerable to opportunistic infection and malignancy). This chapter reviews the complications (namely, GvHD, infection, malignancy, and graft rejection) of solid-organ transplantation on either side of this delicate balance. Special attention is directed toward opportunistic infections and unusual malignancies that occur in the immunosuppressed patient population.

This chapter focuses on complications in solid-organ transplant recipients. There are also individual chapters devoted to each solid organ. Many of the complications seen in solid-organ transplantation can be seen in hematopoietic transplant recipients, as well. However, these complications are discussed specifically in relation to hematopoietic transplant recipients in Chapter 64.

**GRAFT-VERSUS-HOST DISEASE**

GvHD is the phenomenon characterized by the immunocompetent donor’s cells attacking the tissues of the immunocompromised host. It has an incidence of 0.1% to 2.0% with a mortality rate as high as 75%. It is much more common in patient with bone marrow transplant but still occurs in patients with solid-organ transplants [4,5]. It manifests as fever, rash, diarrhea, or hematocytopenia [4].

The condition typically occurs 2 to 6 weeks after solid-organ transplantation as typified in liver or intestinal transplant recipients, but may occur up to 4 months following the transplant [6]. The mechanism is thought to be related to the engraftment of T cells from the donor graft [6]. There is no standard treatment for GvHD. Treatment options have included almost complete withdrawal of immunosuppressive agents,
steroid therapy, antibody therapies, and different types of plasmapheresis. The greatest experience is from bone marrow transplant recipients in whom aside from steroid therapy, extracorporeal photopheresis has also demonstrated therapeutic benefits. This involves subjecting the peripheral blood to phototherapy in an effort to induce apoptosis in mononuclear cells, though this mechanism of action has not been fully validated. The postulated mechanisms involve the following: (1) reduced stimulation of effector T cells; (2) deletion of effector T cells; (3) induction of regulatory T cells; (4) increased anti-inflammatory cytokines; and (5) reduction of proinflammatory cytokines. Photopheresis seems to downregulate the T-cell alloreactivity that plays a significant role in the pathogenesis of GvHD after bone marrow transplant with hemopoetic stem cells [7]. Additional studies and pursuing these therapies with a view to share the results to add to the current cohort of patients who are being treated with this modality are the current recommendations based on a Cochrane review [7].
The suppression of the host immune response is required to establish and maintain a functioning solid-organ graft. The development of immunosuppressive therapies has been impressive, leading to the widespread use of solid-organ transplantation as the primary therapy for a number of organ failure syndromes. This success is associated with an increased susceptibility for a number of serious infectious complications. Up to 80% of solid-organ transplant recipients experience an infectious complication during the first year posttransplant, and infections remain a major cause of morbidity and mortality in the transplant population [8].

The range of potential pathogens that can cause disease in the immunosuppressed host is impressive. Not only are the common endogenous and nosocomial flora involved, but “opportunist” or “atypical” pathogens must also be considered in the differential diagnosis of a solid-organ transplant recipient who has evidence of infection. In considering the epidemiology of infectious complications posttransplant, the clinician must assess numerous factors, including the time posttransplant, the organ transplanted, the type and level of immunosuppression, the need for antirejection therapy, and the potential incidence of surgical complications.

The highest risk of infection corresponds with the period of most intense immunosuppression, which is characteristically during the first 6 to 12 months posttransplant and after antirejection therapy, particularly for recurring episodes of AR. Vidal et al. [8] have characterized periods posttransplant during which certain infection patterns may be seen. Infectious complications in the first month posttransplant are typically caused by endogenous or nosocomial flora that would cause disease in an immunocompetent host [9], including (a) bacterial surgical site infections; (b) postoperative or ventilator-associated pneumonia; (c) urinary tract infections (UTIs) associated with prolonged indwelling urinary catheters; (d) intra-abdominal infections related to surgical complications; and (e) central venous catheter infections.

The infections may be classified as those that affect the graft and those that are systemic in nature. Systemic viral infections such as polyoma virus, BK virus, and cytomegalovirus (CMV) commonly affect the graft as well. CMV may affect other organ systems other than the transplanted graft. These infectious patterns may be categorized into an early cluster
of viral agents occurring with peak frequency between 2 and 3 months posttransplant and a *late cluster* more commonly occurring between 4 and 9 months posttransplant. The early cluster includes CMV [10], adenoviruses [11], hepatitis B virus (HBV) and hepatitis C virus (HCV), and human herpes virus (HHV)-6. The late cluster includes varicella zoster and polyoma viruses. Epstein–Barr virus (EBV) may cause disease throughout the first year posttransplant [12]. The opportunistic fungi can similarly be observed to cluster with *Candida* and *Aspergillus* species (spp), causing infections in the first 2 to 3 months posttransplant [12], whereas *Cryptococcus*, histoplasmosis, coccidioidomycosis, and *P. jiroveci* most often occur later during the first year [13].

After the first 6 to 12 months, most transplant recipients exhibit patterns of infectious disease morbidity that mirrors the rest of the general population, with frequent respiratory infections secondary to pneumococcal infections and influenza, as well as uncomplicated UTIs. However, opportunistic infections can occur anytime. Increased immunosuppression secondary to AR treatment may slightly increase transplant recipients’ susceptibility to, and alter the temporal pattern of, various pathogens. When assessing immunosuppressed transplant recipients for infectious diseases, the clinician must maintain a high index of suspicion at all times. The typical localizing signs of infection and inflammation may be blunted, or even absent, because of the anti-inflammatory action of immunosuppressive regimens.

A key and critical component of the solid-organ transplant process is the preoperative assessment of both the recipient and the donor for any underlying infections, or any disease processes that predispose to infections, that could manifest subsequent to administration of immunosuppressive agents. For the donor, apart from the serologies including HIV, Hepatitis C, and HBV, the most important evaluation is the determination of CMV and EBV status because these two agents are most easily transmitted to a seronegative recipient. For the recipient, a thorough pretransplant history and physical examination are essential to minimize the risk of infectious complications secondary to a latent or indolent infectious process. Routine viral studies should be obtained, vaccinations updated, and prophylaxis administered where indicated (e.g., gut decontamination in liver transplant candidates with end-stage liver disease or prophylactic antibiotics in patients with cystic fibrosis).

**Bacterial Infections**

The first 30 days posttransplant, bacterial infections are common. Even in the immunocompetent patient population, bacterial infections are common complications of surgery. The risk of a nosocomial bacterial infection is related to the site of surgery as well as to the continued
presence of any catheters, lines, endotracheal tubes, or other breaks in the skin. The most common sites of infection are the urinary tract, the surgical site, the lungs, and the bloodstream. The risk of nosocomial bacterial infections is directly related to host factors (including underlying diseases such as diabetes or cirrhosis, obesity, and chronic pulmonary disease) as well as to technical and management factors (including the length and technique of the operation, the development of a hematoma or seroma, and the need for prolonged urinary catheterization, mechanical ventilation, or central venous catheterization).

Renal and bladder-drained pancreas transplant recipients are particularly prone to UTIs. Bacteriuria may be detected in up to 56.7% of renal transplant recipients [14], with an attendant increased risk of systemic sepsis and wound infection. The most common pathogens are gram-negative aerobes, enterococci, and Candida spp. The risk factors associated with an increased incidence of UTIs include prolonged catheterization and hemo dialysis.

Diagnosis of a UTI in transplant recipients is based on clinical suspicion and on urinalysis and culture results. The typical findings of dysuria, hesitancy, and frequency may be absent; the only clinical manifestations might be minimal fever or an elevated white blood cell count. Treatment is often empiric and, because of the risk of bacteremia, should consist of intravenous administration of a third-generation cephalosporin or a quinolone, particularly during the first month posttransplant. Once the offending organism has been identified and antimicrobial sensitivity data are available, treatment should be targeted.

In recipients of solid-organ grafts besides the kidney and bladder-drained pancreas who do not require a long duration of urinary catheterization, an increased risk of bacterial or fungal UTIs is not seen.

Infections of the surgical site are potentially another source of major morbidity and occasionally graft loss and mortality in solid-organ transplant recipients. Surgical site or wound infections are classified according to the structures involved. Infections above the fascia are superficial, infections below the fascia are deep, and combined infections involve elements of both the superficial and the deep compartments of the wound [15].

In all solid-organ transplant recipients, immediately before their operation begins, a single dose of an antibiotic should be administered within an hour of skin incision, to decrease the risk of surgical site infections. In pancreas, bowel, lung, and liver transplant recipients, significant degrees of wound contamination may occur, and so antibiotics are typically administered for 24 to 72 hours posttransplant, although data to support this practice are lacking [16]. In renal transplant recipients, the surgical site infection rate is very low (1% to 2%) and is
comparable to the wound infection rate for other clean-contaminated procedures in immunocompetent patients [15] except in the morbidly obese and diabetic. However, other transplant procedures are associated with higher rates of infection. The wound infection rate after heart transplants is typically below 8%. The rate of wound infections is slightly higher after lung and heart–lung transplants [17]. The rate after liver transplants of superficial wound infections is 6% to 8%; of deep wound infections (most commonly an intra-abdominal abscess secondary to a biliary leak), 15% to 20% [15]. The rate of wound infections after pancreas transplants is high: 10% to 40%, superficial; 15% to 22%, deep; and 8%, combined [18]. Such wound infections confer substantial morbidity, are associated with mortality in some cases, and require a very aggressive approach to diagnosis and therapy.

Pathogenic microorganisms are predictable, according to the type of procedure. In renal transplant recipients, wound infections are caused by the endogenous flora of the skin (gram-positive aerobes) and the bladder (gram-negative aerobes), with occasional Candida spp and enterococci.

In heart transplant recipients, wound infections are almost always due to skin flora such as Staphylococcus aureus and Staphylococcus epidermidis, although some fungal and unusual pathogens are found.

Lung transplants introduce respiratory flora and the potential for grave infections with Pseudomonas aeruginosa.

In liver transplant recipients, wound infections are typically associated with either skin or biliary flora, although any preexisting cirrhosis and end-stage liver disease may result in colonization with drug-resistant nosocomial pathogens.

In pancreas transplant recipients, wound infections are invariably polymicrobial, with gram-positive, fungal, and resistant gram-negative pathogens frequently present. Treatment generally requires opening of the wound, reexploration, and/or administration of broad-spectrum antimicrobial therapy (with carbapenem or extended-spectrum penicillin, a β-lactamase inhibitor, and vancomycin) and often antifungal coverage.

Wound infections are often understated, and findings may be limited to fever, elevated white blood cell count, or wound drainage with a deceptively innocuous appearance. Any wound drainage should be examined by Gram stain and culture; any suspicion or evidence of infections should result in opening of the superficial wound. Additionally, imaging should be undertaken to rule out infections in the deep surgical space; if a fluid collection is identified, percutaneous drainage or prompt exploration is needed. Prolonged, broad-spectrum antimicrobial therapy
is used, and immunosuppression is significantly reduced in the face of potentially life-threatening infections.

The development of postoperative pneumonia varies with the type of transplant and is associated with a high death rate (20% to 60%). Renal transplants are associated with the lowest incidence of postoperative pneumonia (1% to 2%), and lung transplants the highest (22%). The most common pathogens are gram-negative aerobes, staphylococci, and *Legionella* spp. Frequently, *Candida* spp. or CMV may be identified along with bacterial pathogens, particularly in the first 2 to 3 months posttransplant.

Factors predisposing to the development of pneumonia in solid-organ transplant recipients include prolonged mechanical ventilation, thoracic surgery, pulmonary edema, and intense immunosuppression or treatment for AR. Lung transplant recipients are at increased risk, because of their lungs’ preexisting colonization with endogenous flora as well as the loss of mucociliary clearance function associated with denervation [19]. The evaluation of suspected pneumonia in lung transplant recipients should be thorough, including bronchoscopy with biopsies and bronchoalveolar lavage (BAL) to rule out rejection, as will be described. Pleural effusions should be drained and cultured because the progression of an infected effusion to empyema in lung transplant recipients is associated with a very high mortality rate.

Bacteremia in the transplant population, as in the general hospital patients, may occur secondary to seeding along a vascular access device or as a result of hematogenous spread from another source; or, it may be primary (without a source being identified). UTIs, wound infections, and pneumonia are risk factors for the development of bacteremia, as is prolonged vascular catheterization. Other risk factors include receiving a deceased donor graft, leukopenia, and antirejection therapy. Bacteremia in immunosuppressed patients may present as fever, leukocytosis, leukopenia, or hypotension without other significant manifestations. Consequently, routine blood cultures should be part of any workup for fever in this population. Suspicion of bacteremia should prompt removal and culture of intravascular devices and judicious search for a source of other sites of infection. The mortality rate of bacterial sepsis and septic shock in transplant recipients exceeds 50%. Consequently, the use of broad-spectrum antimicrobial therapy, an aggressive approach to source control, and the minimization of immunosuppression are indicated.

There are several atypical bacterial infections that occur in the solid-organ transplant recipients, including mycobacteria such as *Mycobacterium tuberculosis*, *Nocardia* spp, and *Listeria monocytogenes*. Such infections are associated with high rates of morbidity and mortality. Mycobacterial infections are 50 to 100 times more frequent in the transplant population than they are in the general
population and are fatal in 30% of cases. Infections are typically due to reactivation of latent disease or transmission from the transplanted graft. Their diagnosis is complicated by the typical lack of reaction to skin testing seen with immunosuppression. Consequently, a high index of clinical suspicion is needed. If mycobacterial pulmonary infection is suspected, bronchoscopic evaluation with biopsy, acid-fast staining, and culture should be performed. Treatment consists of multidrug therapy with isoniazid, ethambutol, pyrazinamide, and rifampin. Preventive strategies should be considered in patient populations in whom infections are common, in patients with a history of significant exposure without subsequent therapy, and in patients with a history of serious or inadequately treated infections.

Nontuberculous mycobacteria (NTM) such as *Mycobacterium avium* complex, *M. ulcerans*, and *M. xenopi* are environmental mycobacteria that rarely caused disease in humans until the AIDS epidemic of the 1980s. NTM infections typically manifest as insidious pulmonary or soft tissue infections in immunosuppressed patients. If NTM infections are suspected, repeat isolations by bronchoscopy or tissue biopsy are required to improve the chance of diagnosis. In addition to acid-fast staining, a special culture for an atypical mycobacterium should be obtained. Besides continuing antimicrobial treatment, wide debridement of the infected site may be required to eradicate such infections [20].

*Listeria monocytogenes* infection may be associated with pneumonia, bacteremia, or, most worryingly, cerebromeningitis in the transplant population. In renal transplant recipients, *Listeria* spp have been associated with a 26% mortality rate. Consequently, if listeriosis (pulmonary or meningitis) is suspected in any immunosuppressed patient, a thorough evaluation must be performed. Empiric therapy for meningitis should include suitable targeted coverage, such as ampicillin plus an aminoglycoside [21]. The extended-spectrum penicillins also provide adequate coverage.

Nocardial infections most commonly manifest with pulmonary symptoms and signs, but disseminated disease may involve the skin, eyes, and brain, alone or in concert. The clinical manifestations are nonspecific and include fever, chills, malaise, occasional cough, dyspnea, headache, or mental status change. Such infections have a mortality rate of 25% to 50% and must be aggressively diagnosed and treated [21]. The diagnosis is made by microscopic examination of sputum or lung (or occasionally brain) biopsy tissue, or by aspiration of a skin nodule using routine, Kinyoun, and Ziehl-Neelsen staining. Treatment consists of high-dose intravenous TMP-SMX, generally in combination with an aminoglycoside, such as amikacin, with continued treatment with oral TMP-SMX, if possible for life. Concurrently, immunosuppression should be abridged, particularly during treatment of aggressive, disseminated
Fungal Infections

Solid-organ transplants are associated with a significant risk of fungal infections. In the era of broad-spectrum antibacterial prophylaxis and empiric therapy, the incidence of fungi as pathogens is increasing. It is associated with an increased incidence of resistance to azoles as well. Fungal infections are most common after liver and pancreas transplants, with an incidence of 40% [22]. But they are less common after renal transplants (only 5%). Nonetheless, all fungal infections are serious, with an attendant mortality rate, associated with invasive disease, of 30% to 50%. As described previously, most fungal infections occur during the first 3 to 4 months posttransplant, when immunosuppression is greatest. The source of most fungal pathogens is the oral cavity, the gastrointestinal (GI) tract, or the environment.

Candidal overgrowth of the oral and GI tract is common, and prophylaxis consisting of topical nystatin or clotrimazole is often used. Invasive candidal disease is more common in patients with risk factors such as diabetes, neutropenia, intense immunosuppression, and prolonged administration of antibacterial antibiotics, particularly broad-spectrum agents. Long-term TMP-SMX prophylaxis has not been associated with fungal infections. Despite prophylaxis, invasive candidiasis does occur, most often in transplant recipients with a perforation of the GI tract, an anastomotic breakdown, a deep surgical site infection, or a concomitant GI infection, such as CMV gastroenteritis or colitis.

Increasing use of triazoles such as fluconazole has led to more frequent isolation of resistant Candida species, such as C. glabrata and C. krusei. The presence of more resistant strains has necessitated the need for most invasive candidal infections to be treated with amphotericin B or the newer agents like echinocandins (see later). This is a consequence of the attendant morbidity and mortality in the immunosuppressed population [22]. Caspofungin is an echinocandin that acts to block the synthesis of 1,3-β-D-glucan, an essential element of the fungal cell wall. It is well tolerated, with a side-effect profile that compares favorably to amphotericin B. Note that caspofungin and amphotericin B appear to act in an additive manner, and cross-resistance has not been identified [23]. Clinical trials of caspofungin versus amphotericin demonstrated equivalent outcomes in the treatment of candidemia [23]. In solid-organ
transplant recipients, caspofungin will be an important drug in treating serious fungal infections, particularly because it lacks the nephrotoxicity of amphotericin. Two of the more recently released triazole drugs, itraconazole and voriconazole, also possess activity in vitro against *Aspergillus* spp; however, the combination of voriconazole and caspofungin has not been shown to enhance clinical efficacy [24].

Disseminated disease is found in over 50% of cases, with a mortality rate in excess of 80% [25]. Most patients with aspergillosis present with what appears to be a bacterial pneumonia. In high-risk lung or liver transplant recipients, or in lower risk patients whose supposed pneumonia fails to respond to appropriate antibiotic therapy, an aggressive diagnostic approach is urgently needed. The diagnosis of aspergillosis is established initially by microscopic examination of samples obtained via bronchoscopy and BAL for the presence of filamentous hyphae. Agents approved by the U.S. Food and Drug Administration (FDA) against invasive aspergillosis include liposomal amphotericin B, itraconazole, voriconazole, posaconazole, and caspofungin. Dissemination to the central nervous system (CNS) may result in brain abscesses, which in the past were nearly uniformly fatal, but more recently have been successfully treated with newer antifungal agents (such as voriconazole) and some require neurosurgical resection [26].

Infections due to a number of other fungi occur in solid-organ transplant recipients, including *Cryptococcus neoformans*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Zygomycetes* species. Infections caused by those fungi occur in specific settings and present as specific clinical courses that should be considered by the clinician caring for immunosuppressed patients.

*Cryptococcus neoformans* is the second leading cause of invasive fungal infections in liver transplant recipients. This pathogen may cause pneumonia or meningitis, and patients with pulmonary disease often have CNS involvement as well. A high index of suspicion should be maintained, and it is recommended that immunocompromised patients with cryptococcal infection should undergo lumbar puncture even if asymptomatic neurologically. Skin nodules are occasionally seen. The diagnosis is confirmed by India-ink staining and by testing for cryptococcal antigen in cerebrospinal fluid or sputum. Treatment consists of amphotericin B, followed by oral fluconazole, bearing in mind there is increasing resistance to fluconazole over time [27].

*Coccidioides immitis* is endemic in the southwestern United States and in Mexico. Between 7% and 9% of solid-organ transplant recipients residing in that area develop coccidioidomycosis, with an associated mortality rate of 25% in pulmonary cases and of up to 70% in
disseminated cases. The presentation of disease is variable, as multiple organ systems may be involved. The diagnosis must be made by microscopy, antigen detection, or tissue culture. Lifelong fluconazole prophylaxis for solid-organ transplant recipients who reside in endemic areas is advocated in some centers, though long-term outcome data are lacking. A beneficial adjunct in tackling this disease is a reduction of calcineurin inhibitor dosage. The treatment is prolonged amphotericin B administration or azole therapy [28].

Histoplasmosis and blastomycosis infections occur in endemic areas in the Midwest United States, the Mississippi, and Ohio River valleys. Invasive disease, either reactivation of latent fungi or a new infection, occurs in up to 2% of solid-organ transplant recipients, with the highest incidence in those areas. Invasive disease spreads from the lungs to the skin and bone marrow. Biopsy and samples for culture analysis may be obtained from skin lesions or from a bone marrow aspirate. Amphotericin B or itraconazole are appropriate therapeutic agents [13].

_Mucor_ and _Rhizopus_ spp in the Zygomycetes class are soil fungi that, when inhaled, may cause a highly morbid, invasive rhinocerebral infection in profoundly immunosuppressed patients and in diabetic patients with poor glycemic control. The diagnosis is established by biopsy; aggressive surgical debridement is the treatment of choice with adjuvant antifungal therapy (amphotericin B with the occasional addition of 5-flucytosine, itraconazole, or rifampin). The mortality rate associated with those types of infections is in excess of 50% [29].

_Pneumocystis jiroveci_ pneumonia (PJP) is a common cause of pneumonia in immunosuppressed patients. PJP is associated with profound defects in cellular immunity and is normally seen with CD4+ T-cell counts lower than 200 per μL. Those indices are historically seen with OKT3 therapy for AR, which is currently not in use. Prophylaxis with TMP-SMX or atovaquone (if sulfa allergic) makes PJP a rare entity; however, transplant recipients who have a respiratory illness but did not receive prophylaxis (e.g., because of allergy or noncompliance) should be evaluated promptly for PJP. Untreated PJP has a very high mortality rate. The diagnosis is generally established by bronchoscopy and BAL, with methenamine silver staining of washings, or by transbronchial biopsy. Normal findings should not delay further evaluation and therapy, which should be started empirically (the characteristic alveolar and interstitial changes seen on a chest radiograph are late findings). This consists of intravenous TMP-SMX or inhaled pentamidine. Dapsone can be used for patients with sulfa sensitivity.

**Viral Infections**

Viral infections have frequently been recognized as important causes of
morbidity and mortality in solid-organ transplant recipients. Viruses that are endemic and of little clinical concern in the general patient population may produce overwhelming life-threatening infections in the host with suppressed cellular immunity. The recent appreciation of the immunomodulatory effect of several opportunistic viral pathogens gives even more reason for continued development of effective prophylaxis, diagnosis, and treatment modalities for this class of infectious agents. Immunosuppressed transplant recipients may develop serious viral infections by reactivation of latent virus, by transmission of the virus from the donor graft or via blood transfusion, or by exposure to the virus in the environment.

Pathogens known as the HHVs are important in the solid-organ transplant population (Table 65.2). These viruses commonly cause disease during periods of greatest immunosuppression, particularly early posttransplant and after antirejection therapy. They include many of the most important viral pathogens facing immunosuppressed patients, including CMV, EBV, the herpes simplex viruses (HSV), and the varicella zoster virus (VZV).

</table>
CMV infections affect 30% to 75% of solid-organ transplant recipients, primarily within 2 weeks to 3 months posttransplant. The highest hazard for CMV infections is in a CMV-seronegative recipient receiving a graft from a CMV-seropositive donor (the D+/R− graft) [30]. Lung and heart–lung transplant recipients have the highest rate of CMV disease (50% to 80%). The most severe CMV disease is also a primary infection in the D+/R− population. A superinfection (due to concurrent reactivation of an endogenous strain and transmission of a serotypically distinct strain of CMV) is typically intermediate in severity, whereas reactivation of latent disease is most often comparatively mild [30]. The range of clinical disease is vast: from asymptomatic infections (detected solely by a change in anti-CMV titer or by shedding of virus or viral DNA in blood, urine, or sputum) to tissue-invasive disease (which may affect the lungs, liver, or intestine). Clinically, a mild infection produces a mononucleosis-like syndrome, including fever, malaise, and myalgias, often accompanied by leukopenia. More severe disease clinically manifests with differing signs and symptoms, depending on the site(s) of invasive infection. GI ulceration with occasional hemorrhage is seen in GI disease. CMV pneumonitis may produce respiratory insufficiency and failure. CMV hepatitis may lead to liver failure, severe pancreatitis, and critical deterioration of clinical course. CMV retinitis may produce vision
changes, leading to blindness.

Given the high prevalence and significant morbidity of CMV disease, prophylaxis with ganciclovir, valacyclovir, or valganciclovir for 3 to 6 months posttransplant is common, particularly in high-risk patients. Additional prophylaxis is routinely begun with initiation of antirejection therapy. Several randomized clinical trials have shown ganciclovir prophylaxis to be superior to acyclovir prophylaxis in preventing both reactivation and primary CMV disease in solid-organ transplant recipients [31].

A second approach to this problem is the routine close monitoring of at-risk patients with protocol antigenemia or polymerase chain reaction assays followed by empiric (so-called preemptive) therapy with ganciclovir, if levels rise above a predetermined threshold. This approach, though somewhat more cumbersome, has led to reductions in the burden of CMV disease in liver transplant recipients [31]. Prophylaxis, surveillance with empiric therapy, or a combination of both based on calculated risk is currently practiced in most transplant centers. Ganciclovir prophylaxis is used for lung, heart–lung, and heart transplant recipients as well [32], but data on surveillance, preemptive therapy, and efficacy in such recipients are limited. However, there is evidence that there is a tendency toward less CMV disease with the use of mTOR inhibitors [33].

Foscarnet (trisodium phosphonoformate) is used in those rare instances where ganciclovir-resistant strains of CMV are isolated. The data that clearly establish the efficacy of foscarnet in treating CMV disease are limited to CMV retinitis; efficacy equivalent to ganciclovir was observed, but foscarnet was associated with a higher rate of adverse effects (e.g., nephrotoxicity) [30].

The HSVs (HSV-1 and HSV-2) commonly cause mucocutaneous disease of the oropharynx (HSV-1) and the genitalia (HSV-2). In profoundly immunosuppressed patients, they may cause widespread disease, including hepatitis, encephalitis, and pneumonitis. Most such infections are thought to be reactivation of latent virus [34]. The diagnosis is established by identification of the virus by immunofluorescent monoclonal antibody staining or by Tzanck smear. Culture and rising anti-HSV antibody titers provide evidence as well. Treatment consists of acyclovir; most epidermal lesions respond to oral therapy, but any evidence of disseminated disease requires high-dose intravenous acyclovir and minimization of immunosuppression.

Infections associated with EBV are commonly detectable in solid-organ transplant recipients. The most common manifestations include the typical mononucleosis-type syndrome, pneumonitis, and hepatitis. The diagnosis of EBV infections is made by detection of heterophile immunoglobulin M antibodies in serum or by following titers of antibodies
to viral capsid antigen. Polymerase chain reaction is also used to monitor viral activity and response to therapy. Treatment consists of acyclovir (or ganciclovir, when a CMV infection is also suspected). Immunosuppressive de-escalation is necessary in disseminated disease. In a Cochrane review with the use of Belatacept, there was an increased incidence of posttransplant lymphoproliferative disorder (PTLD) in EBV-naive recipients compared with patients receiving calcinuerin inhibitors [35].

VZV commonly emerges from latency in immunosuppressed transplant recipients and causes an episode of shingles [36]. More rarely, VZV may cause disseminated infections, such as pneumonitis and encephalitis. Pediatric transplant patients are routinely inoculated with the varicella vaccine, which has markedly reduced this type of disease; the vaccine is recommended pretransplant for all pediatric and nonimmunosuppressed transplant candidates. VZV infections are treated with acyclovir; with severe disseminated disease, immunosuppression is reduced in addition [37]. No evidence supports the efficacy of anti-VZV immune globulin for treating severe VZV disease in immunocompromised patients.

Co-infection with HHV-6 and association with severe CMV disease has been reported, but understanding causality in this context is difficult. Treatment of neurologic diseases related to HHV-6 includes ganciclovir and foscarnet, either alone or in combination [38]. HHV-7 is not yet clearly associated with clinical syndromes that pose major problems in solid-organ transplant recipients. HHV-8 is linked to the development of Kaposi sarcoma in transplant recipients (vide infra).

Viral hepatitis is a significant problem, particularly in liver transplant recipients, who may have developed end-stage liver disease as a result of HBV or HCV infections. Primary HBV or HCV infections may occur during the transplant operation itself because of donor graft or blood transfusion transmission.

Would-be donors positive for hepatitis B surface antigen (HBsAg) and/or anti–hepatitis B core antibodies (HBcAbs) are often excluded from donating any organ or tissue [39]. Organs other than the liver have been transplanted from isolated HBcAb-positive donors, without evidence of transmission, and the risk for transmission is very low from a review of the literature [40]. HCV-positive donors are normally allowed to donate their livers and kidneys to recipient who are also HCV-positive. Liver transplant candidates with HBV or HCV disease are transplanted; currently, their graft and patient survival rates, particularly in the short term, are comparable to those for recipients without HBV or HCV
disease. HBV disease is no longer a contraindication to a liver transplant; however, the use of lamivudine and HBV-immune globulin (HBIG) has significantly reduced the burden of recurrent HBV disease [41] and has allowed hundreds of patients with end-stage liver disease secondary to HBV to undergo successful transplantation. Continuing HBV prophylactic therapy appears to be the optimal duration strategy in ensuring low or absent viral levels [41].

Up to 25% of hepatitis C–positive transplant recipients accelerate to cirrhosis within 5 to 10 years posttransplant, likely related to immunosuppressive therapy and rejection [42]. The care of transplant candidates with HCV includes extending the donor pool, tailoring antiviral treatment pre- and posttransplant, and offering a living donor transplant [43]. A very effective interferon-free regimen, which obtains high sustained viral response within 8 to 12 weeks of therapy, has proved effective in managing hepatitis C, although the cost is considered prohibitive, with barriers including insurance denials; however, it is much cheaper than liver transplantation. These drugs are currently available for clinical use with very promising results even in those co-infected with HIV [44].

The transmission of HIV via an organ transplant from an HIV-positive donor was described over two decades ago [45]; HIV-positive status will not be contraindication to either donating or undergoing a transplant after passage of the HOPE Act and the enactment of appropriate policies to support the practice [46]. However, solid-organ transplant recipients infected with HIV have been identified and have enjoyed long-term survival posttransplantation [46], given the success of long-term multidrug therapy for HIV. With the introduction of highly active antiretroviral therapy (HAART), the transplant community has now recognized HIV infections as a chronic condition. In fact, end-organ failure develops in HIV-positive individuals as they age and/or from the side effects of their antiviral treatments. Short-term outcomes for HIV-positive transplant recipients have been good even for those co-infected with hepatitis C [47]: the HIV load remains suppressed, CD4+ T-lymphocyte counts are stable, and the risk of opportunistic infection is acceptable. However, major challenges in the care of HIV-positive transplant recipients include high graft-rejection rates and multiple drug interactions between HAART and maintenance immunosuppression regimes [47].

The polyomavirus, including BK, JC, and SV40, is an omnipresent pathogen that has no clinical significance in immunocompetent hosts. BK virus (BKV) is tropic-specific for human transitional and renal tubular epithelial cells. Primary infection occurs early in life; BKV establishes lifelong latency in the host’s renal cells. Reactivation takes place when the host’s immune system is compromised, such as during pregnancy or
posttransplant immunosuppression. The diagnosis is made by detecting free viral particles in the urine, blood, or intranuclear viral inclusion-bearing cells (decoy cells) in urine cytology specimens. BKV nephropathy (BKN) has been increasingly recognized as an important entity in kidney transplant recipients since the mid-1990s; currently, it is seen in 1% to 9% of them within the first year posttransplant. Depending on the severity of renal tubular injury, clinical presentations of BKN can include fatigue, fever, mild hydronephrosis, or marked graft dysfunction. In bone marrow transplant recipients, hemorrhagic cystitis has been described. The diagnosis of BKV reactivation is made by urinary cytology, quantitative polymerase chain reaction (PCR) analysis to measure the viral load in urine or plasma, and kidney biopsy [48]. The mainstays of caring for patients with BKN are to reduce immunosuppression and to closely monitor disease progression. Given the lack of specific antiviral agents against BKV, low-dose cidofovir or leflunomide or fluoroquinolone has been used, with no appreciable effect, in patients with persistent BKN [49].

Human papilloma viruses may cause disease through the development of tissue-specific growth, leading to benign or malignant processes, including cervical cancer, cancer of the vulva and perineum, condyloma acuminatum, laryngeal polyposis, and nonmelanotic skin cancer (vide infra). Respiratory syncytial virus may produce a fulminant pneumonia in both adult and pediatric transplant recipients. The diagnosis is made by nasopharyngeal washing. More severe cases should be treated with ribavirin.

Parasitic Infections

Numerous common parasitic infections are seen in immunosuppressed solid-organ transplant recipients. Toxoplasma gondii presents as a brain abscess with neurologic changes [50]. It is seen late posttransplant, whereas a brain abscess in the early posttransplant period is more likely to be fungal [51]. Heart transplant recipients seem to be at greatest risk, possibly due to the presence of T. gondii cysts in donor myocardial tissue. Positive Toxoplasma is a not a contraindication for organ donation. However, if the heart donor was seropositive for T. gondii, the recipient normally undergoes prophylactic treatment with pyrimethamine and sulfadiazine for 3 to 6 months posttransplantation. Treatment of T. gondii infections consists of pyrimethamine and sulfadiazine; the mortality rate is high in transplant recipients who exhibit CNS disease.
MALIGNANCY

Solid-organ transplant recipients have a distinctly increased risk of developing malignancy posttransplantation. The Israel Penn International Transplant Tumor Registry initiated and has maintained an extensive data collection that tracks the epidemiology of tumors in transplant recipients [52]. The increased incidence of malignancy is multifactorial, probably due to a combination of the activation of latent viruses with oncogenic potential, the direct oncogenic effect of immunosuppressive drugs such as cyclosporine, and, perhaps, environmental factors [53]. Strong but indirect evidence points to the loss of immunologic surveillance as a mechanism of increased oncogenesis. The most common neoplasms of solid-organ transplant recipients are skin cancers, PTLD, lung cancer, Kaposi sarcoma, and carcinoma of the cervix. Of those neoplasms, lung cancer appears to occur at the same frequency as in the general population; the other neoplasms occur at increased incidence in solid-organ transplant recipients. PTLD presents the greatest challenge in terms of attendant high morbidity and mortality rates.

Posttransplant Lymphoproliferative Disorder

PTLD encompasses a very broad range of pathologies, from simple lymphoid hyperplasia to very aggressive monoclonal B-cell lymphomas. EBV infections play a central causal role. In particular, primary EBV infections posttransplant (EBV D+/R– match) and immunosuppression markedly increase the risk of PTLD [12]. Other risk factors include active CMV disease [30], CMV D+/R– match, and increasing intensity of immunosuppression.

PTLD is least common in adult kidney transplant recipients and most common in pediatric small-bowel transplant recipients. It is most common early posttransplant, concurrent with the greatest period of immunosuppression and with the use of anti–T-cell therapy for AR, particularly repeated courses. However, a subset of PTLD occurs late (several years) posttransplant. These late occurring neoplasms appear to be related to patient age, duration, and intensity of immunosuppression, and type of graft than to the more typical risk factors seen in early-onset disease.

The clinical presentation of PTLD varies widely, as might be expected
from the wide range of pathology encountered with this entity. Many patients experience fever, sweats, and myalgias as the only symptoms. Weight loss, diarrhea, and upper respiratory infection are common symptoms; some, but not all, patients have lymphadenopathy. CNS involvement, which occurs in up to 20% of patients [54], often manifests as mental status changes. GI disease may be silent or may present as abdominal pain, GI bleeding, and perforation with peritonitis, or bowel obstruction. Intrathoracic PTLD has a characteristic radiographic appearance of multiple circumscribed pulmonary nodules, which may or may not be accompanied by mediastinal lymphadenopathy. PTLD in the graft itself can present very similarly to AR; because the therapeutic approach to those two entities is diametrically opposed, a correct diagnosis by biopsy is essential.

The gold standard for establishing the diagnosis of suspected lesions in PTLD is biopsy. These specimens are histologically graded (based on cell morphology and nodal architecture) and assessed for clonality (polyclonal or monoclonal) and for the presence of an EBV genome and copy number. Specific cell marker studies are required to establish the clonality, but most lesions are EBV positive and of B-cell lineage. Experienced pathologists with working knowledge of PTLD as well as with graft rejection and opportunistic infections should review the biopsy. Consensus conference standards for the grading and classification of PTLD have been used [55]. Histologic classification currently uses the Harris standard formulation [56,57]. EBV serology does not typically add to the diagnostic workup of PTLD, with many false-negatives in patients with established primary EBV infections. Similarly, peripheral cytology is not helpful in making the diagnosis and molecular techniques need to be employed [56]. If PTLD is suspected, patients should undergo imaging of the head, thorax, and abdomen. Fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT scanning has high specificity as a diagnostic and/or staging tool and in follow-up studies of PTLD patients [56].

Currently, there is little information to provide direction regarding optimal prophylaxis for PTLD. Clearly, it is important to identify, and closely monitor, high-risk patients (e.g., children; liver and small-bowel transplant recipients; EBV-negative transplant recipients, particularly those with an EBV-positive donor; transplant recipients on intense antilymphocyte therapy for rejection). Both antiviral agents and passive immune transfer with CMV-IVIG immune globulin have been used as prophylaxis against PTLD, with no proven efficacy. Several trials are ongoing to establish the best prophylactic approach. Reduction of the immunosuppressive regimen with evidence of rising EBV titer has shown to be helpful when compared with historical controls [56].

Treatment of established PTLD depends on each patient’s clinical situation and histologic diagnosis. With few trials to guide therapy, a
gradual, individualized approach is taken. Ordinarily, immunosuppression is reduced to the barest minimum, and specific therapy is directed at the neoplasm. In 25% to 50% of patients, PTLD often regresses after immunosuppression is reduced [56].

Surgical intervention is clearly indicated for patients with GI PTLD that manifests as aggressive disease (e.g., viscus obstruction or perforation). Surgical debulking of the tumor burden has also been used in amenable cases, as has radiotherapy. Isolated CNS disease initially should be treated with external beam irradiation [56].

Medical approaches to treating PTLD include (a) antiviral medications (e.g., acyclovir, ganciclovir); (b) interferon-α2b; (c) immunoglobulins (d) standard, low-dose, and high-dose chemotherapy protocols; and (e) most recently, monoclonal antibodies directed against B-cell surface markers, such as CD19 and CD20 (rituximab). In unusual cases, immunomodulatory therapy with adoptive transfer of cytotoxic T cells sensitized to EBV has been attempted with some success [56].

Late-onset PTLD, occurring more than 1 to 2 years posttransplant, often does not respond to the reduction in immunosuppression and to the medical therapy typically used in patients with early-onset disease. Often EBV-negative, late-onset PTLD is difficult to treat because of side effects, including infectious complications of the aggressive chemotherapy that is often required. Similarly, CNS involvement may be a marker for PTLD that is potentially refractory to therapy, possibly because of the relatively privileged immune site. Therapeutic options include intrathecal administration of interferon-α and anti–B-cell antibody therapy in addition to local radiotherapy, but the prognosis remains guarded [56].

Skin Cancer

Nonmelanotic skin cancers are the most common neoplasms associated with transplantation and immunosuppression. Increased incidence is associated with increasing time posttransplantation and sun exposure. Often-quoted studies show a prevalence of 66% in transplant recipients in Australia after 24 years of surveillance [58] and 40% after 20 years in the Netherlands [59]. Those figures correlate to a 4- to 21-fold increase in prevalence in transplant recipients, as compared with the immunocompetent population, with synergistic increases seen in the areas of highest sunlight exposure in countries such as Australia [53].

Squamous cell carcinoma is the most common skin cancer in transplant recipients. Many recipients develop multiple lesions; the transplant patients are generally younger when compared with members of general population. The incidence of melanoma is also 2.4 times higher than the general population [60]. Even nonmelanotic squamous cell
Carcinomas behave more aggressively in transplant recipients, with lymph node metastasis and a 6% mortality rate due to disseminated disease [61]. On identification of skin lesions, prompt surgical excision should be undertaken. Solid-organ transplant recipients are instructed to avoid direct exposure to sunlight for any prolonged period of time and to liberally use sunblock. Clearly, close dermatologic counseling, education, and follow-up are warranted in this patient population [62].

Kaposi Sarcoma

Kaposi sarcoma (KS) is a nodular vascular neoplasm commonly seen cutaneously but may be multicentric involving visceral tissues (such as the lungs and GI tract). Endemic in the Mediterranean region and Middle East, it is strongly associated with either endogenous or exogenous immunosuppression, as a result both of AIDS and of immunosuppressive therapy. The incidence of this disease in U.S. transplant recipients is 0.4%, which represents a 20-fold increase over the basal rate in the population at large [63]. Recently, HHV-8 has been implicated as a causal agent in KS.

Cutaneous KS is easily identified by clinical appearance and biopsy. But patients with only visceral KS often present with more advanced disease, usually GI bleeding or viscus perforation, sometimes dyspnea related to pulmonary disease. Immunosuppression should be reduced to the greatest extent possible, after which about 30% to 55% of patients will experience remission. Chemotherapy is reserved for patients with visceral KS and for those who do not experience remission after their immunosuppression is reduced. However, of patients with visceral KS, 45% to 50% die of it [64]. Anecdotal evidence indicates that certain patients may respond to antiviral agents (e.g., ganciclovir).

Cervical Cancer

The incidence of cervical intraepithelial neoplasia is elevated by 10- to 14-fold in solid-organ transplant recipients and may approach 50% [65]. Cervical carcinoma was seen in 10% of all women with posttransplant cancer in the Transplant Tumor Registry [52]. Close surveillance by pelvic examination and Papanicolaou smear is essential in this population, given the increased incidence of disease. In the posttransplant patient with potentially advanced cervical cancer, there is no standardized approach.
Transmitted and Recurrent Malignancy

Thankfully the transmissions of malignancy from grafts are not widespread, but when it does occur it is potentially devastating. Case reports have described patients who received grafts that harbored malignant cells, leading to the development of malignancy. Transmission to transplant recipients of renal cell carcinoma, metastatic cancer of the breast or lung, and melanoma has been reported. Currently, cancer or recent history of cancer is a contraindication to organ donation, with the possible exception of some low-grade skin cancers, noninvasive CNS neoplasms, and small, limited cancers that has been excised and is not likely to recur or spread. Nonetheless, some grafts are found to contain foci of neoplasia, which develop into a clinically significant cancer in recipients. This finding emphasizes the need for a thorough examination of donors during organ procurement, particularly considering the present trend toward the use of older donors.

Patients with a history of malignancy are clearly at risk for recurrent disease posttransplantation, presumably due to the use of immunosuppression. Data from the Transplant Tumor Registry show a 21% recurrence rate, with the highest rates seen in patients with multiple myeloma (67%), nonmelanotic skin cancer (53%), bladder cancer (29%), soft tissue sarcoma (29%), renal cell cancer (27%), and breast cancer (23%) [66], and there is a tendency to using organs with small, incidental renal cell carcinoma may be reasonable [67]. Tumors were least likely to recur if more than 5 years had passed between cancer treatment and the transplantation.

Liver transplantation to treat patients with primary, well-circumscribed liver tumors represent a special case. In this population, liver tumor size and the number of liver tumors are considered indicative of the likelihood of disease recurrence and patient survival posttransplantation. Adjuvant techniques, such as cryoablation and radiofrequency ablation, to reduce the tumor burden pretransplantation have been used, but currently the data are insufficient to clearly define the ability of adjuvant techniques to reduce posttransplant morbidity and mortality secondary to disease recurrence. Risk factors for recurrence include tumor size >6 cm, number of nodules >5, and vascular invasion per the final pathology report [68]. Clearly, tumor biology dictates the risk of disease recurrence [69].
REJECTION

The human immune system is an evolutionarily more advanced, adaptive, efficient, “specific,” and versatile host defense mechanism against the invasion of pathogens as compared with the nonspecific innate immune system of invertebrates. However, a side effect of the ability of the host immune system to recognize and attack “nonself” tissues is rejection of grafted tissues posttransplantation. That side effect was observed clinically for centuries before Medawar demonstrated that it was an intrinsic property of the host immune system in response to foreign tissue [70]. The exogenous modulation of the host immune system to allow sustained graft function has proceeded along with—and often preceded—our understanding of the physiologic mechanism of rejection and tolerance.

Understanding the immune system is integral to our understanding of rejection. The immunologic disparity among members of the same species of mammals that leads to lack of recognition of “self” tissue and to rejection of nonself tissue is based on the differences in cell surface molecules that are expressed. In humans, these major histocompatibility antigens were first identified on leukocytes, and hence are termed human leukocyte antigens (HLAs). HLAs are subdivided into two classes: class I (HLA-A, -B, and -C), expressed on the surface of all nucleated cells, and class II (HLA-DR, -DQ, and -DP), expressed on the surface of antigen-presenting cells (APCs). The recognition of nonself tissue occurs via two distinct immunologic pathways: direct and indirect allorecognition. Direct allorecognition consists of recipient T-helper cells recognizing donor HLA disparity expressed on the donor cell surface. Indirect allorecognition consists of recipient APCs (e.g., activated macrophages, dendritic cells, B lymphocytes) phagocytosing donor cellular debris, including HLAs, which are then processed and re-presented on the APC surface to be recognized by recipient T-helper cells (CD4⁺ lymphocytes) (Fig. 65.1).
In either pathway, costimulation signals between CD4\(^+\) T-helper lymphocytes and CD8\(^+\) cytotoxic T lymphocytes trigger a cascade of immunologic events. Interleukin (IL)-2, an important and early signal in immune activation, is secreted by activated CD4\(^+\) T-helper lymphocytes, stimulating increased T-cell responsiveness, clonal expansion of alloreactive T lymphocytes, and acquisition of the cytolytic phenotype by host T lymphocytes. Direct allorecognition leads to a more immediate and vigorous immune response against foreign tissue, but, in both pathways, additional helper T lymphocytes are recruited and secrete a wide array of cytokines (e.g., IL-1, interferon-\(\gamma\), tumor necrosis factor-\(\alpha\)), facilitating the further recruitment of cytotoxic T lymphocytes, natural killer cells, and B lymphocytes. Then, B lymphocytes begin to secrete antibody directed against the allogeneic tissue in ever-increasing quantities. Rejection mechanistically occurs by infiltration of the graft by effector cells, the binding of antibody, and the activation of complement. Unchecked, the phenomenon inexorably leads in graft loss (Table 65.1).

Donor–recipient mismatches between HLAs may produce an immune response by either the direct or indirect pathways; however, minor non-HLA mismatches typically produce an immune response by the indirect pathway only.

Rejection is classified according to the temporal relation between the implantation of the graft and its dysfunction supported by the histologic features seen in allograft. The three main types of rejection are hyperacute (HAR), acute (AR), and chronic (CR). Each type is mediated by a different host immune mechanism. Consequently, each type poses different problems for the patient, clinicians, and pathologists.
Hyperacute Rejection

HAR occurs within a few minutes to a few hours after the reperfusion of the graft. Preformed antibodies directed against antigens presented by the graft mediate activation of complement [71], activation of endothelial cells, and formation of microvascular thrombi, leading to graft thrombosis and loss [71]. The process is irreversible; currently, no treatment is available. Because HAR is mediated by circulating preformed antibodies normally directed against ABO system (comprising the four main blood types, i.e., A, B, AB, and O) antigens or against major HLA antigens, thorough screening of potential transplant recipients and strict adherence to ABO verification policies should prevent nearly all HAR.

The panel-reactive antibody (PRA) assay is a screening test that examines the ability of serum from potential transplant recipients to lyse lymphocytes from a panel of HLA-typed donors. A numerical value, expressed as a percentage, indicates the likelihood of a positive cross-match to the donor population. Therefore, patients lacking preformed antibodies to random donor lymphocytes are defined as having a PRA of 0% and have a very low probability of eliciting a positive lymphocyte cross-match to any donor. The finding of a higher PRA identifies patients at higher immunologic risk for a positive cross-match and thus for HAR and for subsequent graft loss. Most often, such patients were previously sensitized by childbirth, blood transfusions, or prior transplantation.

Pretransplantation, cross-match testing is performed to identify preformed antibodies against class I HLAs (T-lymphocyte cross-match testing) and class II HLAs (B-lymphocyte cross-match testing). In renal and pancreas transplantation, a strong positive class I-HLA cross-match immediately pretransplant is ordinarily an absolute contraindication. At most centers, heart and liver transplantations are performed without a cross-match, unless the recipient is highly sensitized or has previously received a graft possessing major antigens in common with the current donor (i.e., donor-specific antibody [DSA]). A positive B-lymphocyte cross-match indicates preformed antibodies directed against class II HLAs and is a relative, but not absolute, contraindication to a transplant. Recent studies confirmed the efficacy of plasmapheresis followed by administration of immune globulin to reduce PRA levels and to convert strongly positive cross-match results to weakly positive or negative results, thereby allowing organs to be transplanted across what were previously considered as strong immunologic barriers [72].

Cross-match testing helps clinicians to identify the presence of antibodies against potential donor antigens and to assess the risks of posttransplant rejection and subsequent graft loss. However, these cross-matching assays are not standardized. Since the mid-1960s, cross-match
testing was based on the complement-dependent cytotoxicity (CDC) assay. The CDC assay was further refined by adding a wash step and an antihuman globulin step, to increase its sensitivity and specificity. Then, with the introduction of technology based on flow cytometry (FC), the presence of recipient antibody on the surface of donor lymphocytes could be detected independent of complement binding.

One of the latest developments in anti-HLA antibody screening was the introduction of Luminex technology, using HLA-coated fluorescent microbeads and FC. This method in theory pinpoints the DSAs in sera of recipients with high PRA levels. Because all transplant donors are currently HLA typed, a negative cross-match for recipients with high PRA levels can be ensured by avoiding the selection of donors carrying unacceptable HLA antigens (virtual cross-match) [73].

The main concerns with these new developments in antibody typing and cross-match testing are between-center test variability and the thresholds of defining false-negative results (results that could deny recipients with high PRA levels a chance for a potential lifesaving transplant). Currently, it is up to an individual transplantation center to implement its own HLA typing and cross-matching policies, depending on the center’s experience, clinical outcomes, and risk tolerance.

Although screening has all but eliminated HAR as a clinical problem, active investigation is nonetheless directed at dissecting the underlying pathophysiologic mechanisms of HAR. Another research focus is on the similar rapid rejection of xenoreactive antigens that serve as a barrier to the development of xenotransplantation.

**Acute Rejection**

AR is the most common form of graft rejection in modern clinical transplantation. It may develop at any time, but is most frequent during the first several months posttransplant. Rarely, it occurs within the first several days posttransplant, a process termed *accelerated acute rejection*, most likely a combination of amnestic immune response driven by sensitized memory B lymphocytes and activation of the direct allore cognition pathway. Under such circumstances, the donor antigen exposure often occurred in the distant past, and so the level of circulating DSAs would have been too low to be detected by conventional cross-matching techniques. Once challenged by the same donor antigens introduced by the organ transplant, dormant memory lymphocytes reactivate, replicate, and differentiate. Within several days, large numbers of antibodies are directed against the donor allograft resulting in graft rejection.
AR may be cell mediated, antibody mediated (AMR), or very occasionally mixed. However, they are not mutually exclusive. Histologically, AR generates an infiltration of activated T lymphocytes into the graft, resulting in gradually progressive endothelial damage, microvascular thrombosis, and parenchymal necrosis. Pathologic grading schemes have been developed regarding the extent to which AR involves vascular damage, cellular infiltration, or a combination of both. Vascular AR is thought to be mediated by the presence of DSAs, albeit not in sufficient numbers to cause HAR. C4d, a complement split product detected immunohistochemically in the capillaries of biopsied graft specimens, is highly correlated with AMR [74]. Without intervention, AR inevitably progresses to graft loss. The clinical presentation of AR varies markedly, depending on the specific organ, on the level of immunosuppression, and on the attendant level of inflammation in the affected tissues.

Unless the host immune system is adequately suppressed pharmacologically, transplantation inevitably leads to AR. A combination of immunosuppressive agents is typically used chronically to prevent AR, including a lymphocyte antagonist (usually a calcineurin inhibitor [CNI] such as cyclosporine or tacrolimus) and an antiproliferative agent (such as azathioprine or mycophenolate mofetil), with or without corticosteroids. Antilymphocyte antibody therapy is often added during induction of immunosuppression or for treatment of “steroid-resistant” AR.

In the last decade, immunosuppression for transplant recipients has been undergoing a paradigm shift. Since the mid-1990s, the use of antibody induction in solid-organ transplant recipients has increased from 25% to more than 90% [75]. Monoclonal antibodies such as basiliximab and daclizumab (both anti-CD25 [IL-2 receptor]) use has declined in the face of increasing use of T-cell depleting agents. Daclizumab is no longer on the market. Furthermore, strategies such as corticosteroid avoidance and CNI-reduced or CNI-free maintenance immunosuppression were shown to be equivalent to traditional triple-drug maintenance [76]. Nonetheless, all immunosuppressive agents carry some risk of toxicity and adverse reactions that may complicate therapy (Table 65.3).

Chronic Rejection

CR is a largely frustrating and poorly understood clinical phenomenon, with slightly different manifestations in each type of graft. Over time, the accumulation of microvascular injury in a graft degrades graft function, with eventual graft loss. This process appears to be mediated by multiple
mechanisms, likely including both immune and nonimmune factors. Evidence for the contribution to CR of immune factors includes the observation that AR episodes significantly increase the likelihood of CR as well as the correlation, observed in renal transplant recipients, between a poor response to AR treatment and the subsequent development of CR [77]. A similar association between a poor response to AR treatment and the subsequent development of CR has been observed in liver transplant recipients, although reversible AR has little impact. Nonimmune factors also likely contribute to the development and progression of CR, including the toxic effects of immunosuppressive medication and cumulative injury from infection such as that caused by cytomegalovirus (CMV) [78]. CR nearly always eventuates in graft loss, although the rapidity of the process varies considerably.

**Renal Grafts**

AR occurs in 10% to 25% of renal transplant recipients. Because most episodes are clinically silent, the diagnosis of AR must be considered in recipients whose serum creatinine, blood urea nitrogen, and urinary output values have normalized and whose graft function has been stable in the outpatient setting, but whose serum creatinine and blood urea nitrogen values subsequently rise while their urinary output decreases. The presence of hypovolemia, drug nephrotoxicity (e.g., high calcineurin levels), ureteral obstruction or leak, lymphocele, or vascular anastomotic complications should be excluded, and the diagnosis of AR should be established via histologic examination of a percutaneous graft biopsy specimen. Rarely, tenderness and swelling in the area of the graft occur, and occasionally fever or other signs of systemic inflammation, although such findings used to be common.

A high degree of clinical suspicion should be maintained for recipients who experience delayed graft function, as up to 30% exhibit evidence of AR on biopsy; 20% of recipients who require dialysis posttransplant have AR [79]. Intriguingly, up to 30% of recipients with well-functioning grafts also have AR, per early posttransplant protocol biopsies, but whether such findings are clinically important and whether mild episodes should invariably be treated remain controversial [80]. Recent studies have provided data that may allow prediction of individual risk of AR, with the potential for individualizing immunomodulatory therapy. For example, a donor IL-6 genetic polymorphism is strongly associated with an increased incidence of AR posttransplantation [81].

The diagnostic workup for AR includes studies that may identify alternative causes of recipient graft dysfunction (Table 65.4). It is vital to consider alternative diagnoses, particularly in the early postoperative period, including vascular problems with the arterial or venous
anastomoses, ureteral obstruction, or urinary leak. Other common causes of apparent graft dysfunction include the acute tubular necrosis associated with delayed graft function, hypovolemia and attendant prerenal azotemia, and the nephrotoxic effects of cyclosporine and tacrolimus. To rule out the vascular and ureteral problems discussed previously, a duplex ultrasound study of the renal graft is commonly obtained. Several ultrasound findings may suggest the diagnosis of AR: increased size of the graft, increased cortical thickness, enlargement of the renal pyramids, and decreased graft renal artery blood flow [82]. The resistive index has not been shown to be significant in helping with the diagnosis [83]. The diagnosis of AR is clearly established by percutaneous allograft biopsy and histologic examination. Biopsy is generally safe when performed by an experienced practitioner; however, complications include bleeding, hematoma and arteriovenous fistula formation, and ureteral or major vascular injury.

| TABLE 65.4 Basic Workup of Recipients with Graft Dysfunction or Acute Rejection |
|--------------------------------|------------------------------------------------------------------------------------------------|
| History and physical examination | Establish and order differential diagnosis |
| Doppler ultrasound | Rule out vascular surgical complication |
| | Rule out leak (e.g., biliary, ureteral) |
| Serum chemistry | Evaluate relative blood urea nitrogen and creatinine, amylase, bilirubin, etc. |
| | Detect and treat electrolyte abnormalities |
| Drug levels | Evaluate for potential drug toxicity |
| | Detect inadequate |
Rejection is graded according to the modified Banff Criteria, which may be used to guide therapy that has been expanded to include C4d negative antibody–mediated rejection [84]. Fine-needle aspiration biopsy has been used by some centers to establish the diagnosis of AR; however, some consider the loss of microstructural data, as compared with traditional core biopsy, to be a weakness of the technique. In particular, the diagnoses of acute vascular rejection and CR are difficult to make using fine-needle aspiration biopsy.

The treatment of AR in renal transplant recipients is not standardized and varies between centers. High-dose methylprednisolone (500 to 1,000 mg per day or every other day [2 to 3 doses] is common) is often the initial approach. Corticosteroid-resistant AR, or AR that is histologically graded as severe or vascular, is often treated with potent depleting antilymphocyte antibodies such as polyclonal antithymocyte globulin (antithymocyte gamma globulin, thymoglobulin). Since some AR episodes occurred while the recipients were on stable immunosuppression, their maintenance therapy was switched from cyclosporine to tacrolimus or from azathioprine to mycophenolate mofetil. Most AR episodes are reversible with current therapies; however, as noted previously, the long-term outlook for preservation of graft function is lessened with each episode, especially when the posttreatment serum creatinine level does not return to the pre-AR baseline.

CR in renal transplant recipients is a frustrating clinical problem and appears to be multifactorial, with immunologic and nonimmunologic factors driving the gradual loss of graft function. As described earlier, minimizing the frequency and severity of AR episodes is important in decreasing the likelihood of eventual CR. Nonimmunologic factors thought to contribute to CR include (a) episodes of infection, particularly due to CMV and BK virus (vide infra); (b) the nephrotoxicity of CNI therapy; (c) ischemia-reperfusion injury and delayed graft function in the peritransplant period; and (d) innate cell senescence within the graft from donor-derived factors [85]. Attention is being directed toward identifying inflammatory activity within the graft, in response to both immune and nonimmune insults that may contribute to the development of CR. One of the leading causes of kidney retransplants is CR. It remains a formidable problem that is still poorly understood. Chapter 57 is
Hepatic Grafts

The transplanted liver is considered to be immunologically “privileged” in that evidence of some degree of immune tolerance occurs in a substantial number of liver transplant recipients over time. Despite that observation, all forms of rejection can occur posttransplant. At one time, it was thought that HAR did not occur in the hepatic graft; this idea is now known to be incorrect, as anti-HLA antibody–mediated HAR has been described in liver transplant recipients [86]. Unlike the renal graft, the hepatic graft undergoes HAR over a number of days, not minutes to hours, probably secondary to its ability to absorb a large amount of antibody and its functional reserve before the onset of the significant microthrombosis and vascular damage seen in HAR. A more delayed form of antibody-mediated rejection is seen in up to 33% of patients who undergo liver transplants across ABO-incompatible blood groups, but even this barrier appears surmountable with the use of plasmapheresis along with aggressive immunosuppression.

AR remains an important clinical problem in liver transplantation; even with the use of standard multiagent immunosuppression, the incidence of AR ranges from 30% to 80%. In two large, multicenter trials, double therapy with a CNI and steroids resulted in a 60% to 80% incidence of AR [87]. The most common liver transplantation regimen consists of two doses of a monoclonal anti-IL2 receptor (basiliximab) as induction therapy and dual maintenance therapy with the CNI tacrolimus and the antimetabolite mycophenolate mofetil, which lessens the incidence and severity of rejection without increasing infection rates [88].

The diagnosis of AR in liver transplant recipients is normally suggested by elevated levels of transaminases, bilirubin, or alkaline phosphatase. Among patients with T-tube drainage (which is increasingly uncommon), the biliary drainage may be seen to thicken, darken, and decrease in amount. The suspicion of AR mandates graft biopsy and studies to eliminate other possible causes of early hepatic graft failure. Duplex ultrasonography and, in some cases, cholangiography are increasingly being replaced by magnetic resonance imaging. Biopsy findings are classified, according to a standardized set of criteria, as mild, moderate, and severe, with clear implications for prognosis [89]. AR is normally treated with high-dose corticosteroids, but 5% to 10% of cases are steroid
resistant; such recipients are then treated with an antilymphocyte antibody or tacrolimus at higher levels.

CR in liver transplant recipients is characterized by vascular obliteration and bile duct loss (“the vanishing duct syndrome”). This is seen in 5% to 10% of recipients, it is more common in those with vasculitic findings during AR episodes; if larger vessels are not seen on biopsy, the diagnosis of CR may be misread as AR. Tacrolimus has been used to salvage grafts in recipients with CR on cyclosporine-based immunosuppression, with a 73% success rate [90]. Chapter 58 is devoted to liver transplantation.

**Pancreas Grafts**

Diabetic patients undergo pancreas-alone (PTA), pancreas-after-kidney (PAK), or simultaneous pancreas–kidney (SPK) transplants and receive more potent immunosuppression than do renal transplant recipients, supported by initial studies demonstrating a higher rate of AR after pancreas transplantation. Overall success rates continue to improve: the risk of AR has been reduced by standardized induction therapy with antilymphocyte antibody preparations, and it may be further reduced with mammalian target of rapamycin (mTOR) inhibitors and/or with IL-2 receptor monoclonal antibodies [91].

Establishing the diagnosis of AR in pancreas transplant recipients can be difficult. Hyperglycemia is a late finding that only occurs with substantial loss of functional islet-cell mass. By the time hyperglycemia is seen, it may be too late to salvage a functional graft. Clinical findings may include fever and graft tenderness; however, pancreas graft rejection is often clinically silent.

For pancreas grafts transplanted along with a renal graft, a rising creatinine level is often used as a surrogate marker of rejection, with antirejection therapy aimed at both the pancreas and the renal allograft. However, isolated pancreas graft rejection is observed in up to 20% of simultaneous pancreas–kidney transplant recipients who have AR [92,93].

Advantages of a bladder-drained pancreas is the use of a decreasing urinary amylase level as a marker of graft rejection [94]. Other possible markers of rejection (serum anodal trypsinogen, serum amylase, soluble HLA, and analysis of glucose-disappearance kinetics during a brief glucose tolerance test) have been examined but have failed to gain widespread acceptance [93].

The diagnosis of pancreas graft rejection is confirmed by biopsy, which may be performed percutaneously or, in bladder-drained recipients, through a cystoscopic, transduodenal approach. Complications (bleeding, arteriovenous fistula formation, graft pancreatitis) have been described,
but most biopsies do not lead to complications. Pancreas transplant recipients with early evidence of graft dysfunction should undergo Doppler ultrasonography to rule out graft thrombosis, which occurs in up to 10% to 20% of grafts [95].

Treatment of AR for pancreas transplantation recipients is similar to that for renal or liver transplantation recipients. High-dose corticosteroids are given initially, with a low threshold maintained for possibly switching to antibody-based therapy, given the relatively common steroid resistance. Most AR episodes are reversed with treatment. Chapter 61 is devoted to pancreas transplantation.

**Intestinal Grafts**

There is no serum test for intestinal transplantation rejection. As a result, biopsy of the intestinal allograft is the gold standard for diagnosis (via ostomy initially). It has the highest rates of AR and GvHD among all solid-organ transplants. The results have markedly improved over the past two decades: at 1 year, patient survival rates of intestinal transplants alone are >80% and of multivisceral transplants are >70%; the respective graft survival rates are >60% and >50%. Although treatment protocols for AR have significantly improved, chronic rejection remains a major issue because of its poorly understood nature in intestinal transplantation. Chapter 62 is devoted to intestinal transplantation.

**Cardiac Grafts**

Rejection in heart transplant recipients is a significant cause of morbidity and mortality among these patients and accounts for up to a third of the deaths. All forms of rejection are seen in heart transplant recipients. Albeit rare, HAR due to preformed antigraft antibodies occurs within minutes to days; it manifests with rapid deterioration of cardiac function, with prolonged need for inotropic support. In recipients whose grafts fail to recover rapidly, an attempt to reverse HAR by plasmapheresis may be made, but success is uncommon, and an immediate retransplant is usually required.

AR in heart transplant recipients is common and usually occurs in the first 3 to 4 months posttransplantation. At one time, the diagnosis was made on the basis of the development of congestive heart failure or the elaboration of electrocardiographic abnormalities. However, the present-day routine of protocol endomyocardial biopsies has eliminated such late findings of AR, except in noncompliant recipients. Most centers use frequent percutaneous transjugular right ventricular endomyocardial biopsies as part of a standardized surveillance protocol. Biopsies are evaluated histologically, according to an international grading system [96], and therapy is directed accordingly.
Several investigators have developed noninvasive approaches to establishing the diagnosis of AR, including electrophysiographic frequency analysis, nuclear scintigraphic techniques, and echocardiography; however, no approach has attained sufficient sensitivity to eliminate the need for protocol biopsies. The need for continued endomyocardial biopsies later than 1 year posttransplantation is controversial and center specific, with most choosing to discontinue its performance of biopsies at 1 year unless indicated on clinical grounds.

The treatment of AR is based on histologic findings. High-dose steroid bolus therapy is used in lower-grade rejection without hemodynamic compromise; oral prednisone therapy for mild AR also has been used with success [97]. Salvage therapy with an antilymphocyte antibody agent is most common in recipients with histologic findings of more severe rejection, in recipients with steroid-resistant rejection, and in recipients with signs of hemodynamic compromise.

Other approaches include switching from cyclosporine-based to tacrolimus-based immunosuppression in recipients with refractory AR in an effort to rescue the graft, a strategy that was proved to be safe and efficacious [97]. Photopheresis has been used in the treatment of recipients with T-cell lymphoma and autoimmune disease. Studies of photopheresis and triple-drug immunosuppression have provided evidence of a decrease in the total number of AR episodes, as compared with triple-drug immunosuppression alone [97].

CR manifests in heart transplantation recipients as cardiac allograft vasculopathy (CAV), an entity that is the major cause of late-term morbidity and mortality. The pathologic findings of CAV include progressive intimal thickening in a concentric manner, which begins distally within the cardiac vasculature. It is associated with the loss of response to endogenous (and pharmacologic) vasodilators [97]. CAV is thought to be immunologically mediated because HLA donor-related matching is clearly associated with reduced rates of CAV but it could be ameliorated with the use of sirolimus [98]. In addition, nonimmunologic mechanisms are thought to be involved; identifiable risk factors for CAV include hyperlipidemia, donor age older than 25 years, recipient weight gain, CMV disease, preexisting donor or recipient coronary artery disease, and increasing time posttransplantation [97]. Another nonimmunologic risk factor for CAV is ischemic time during the peritransplant period. Chapter 60 is devoted to heart transplantation.

Lung Grafts
The lung graft is highly immunologic organ and as a result prone to rejection—nearly all lung transplant recipients experience at least one AR episode. The clinical difficulty posed by rejection is in distinguishing it from other causes of decreased graft function, most commonly infection. HAR of the lung graft [99] is mediated by recipient-preformed antibodies to the donor graft, in a fashion similar to other organs. The clinical manifestation is similar to the more common ischemia-reperfusion injury, which, unlike HAR, usually resolves. HAR of the lung graft is rare and only described in case reports. HAR is uniformly fatal in lung transplant recipients. It must be prevented via initial cross-match testing and exclusion of immunologically unsuitable donor organs and strict adherence to ABO verification policies.

Most AR episodes occur during the first 3 to 6 months posttransplantation. Some recipients experience symptoms, including fever, cough, and dyspnea. Early diagnosis of AR in lung transplant recipients is essential: untreated AR can lead to respiratory insufficiency or failure, and repeated AR episodes are associated with an increased risk of bronchiolitis obliterans and eventual graft failure [99].

Transbronchial biopsy is the gold standard for establishing the diagnosis of AR, although less invasive techniques continue to be assessed [99]. Bronchoalveolar lavage (BAL) is also performed to rule out infection before increasing immunosuppression; infection and rejection may occur simultaneously in up to 25% of lung transplant recipients with AR [99]. Early diagnosis of AR may be aided by spirometry; decreases in timed forced expiratory volume, in pulmonary capillary blood volume, and in the diffusing capacity of the lungs for carbon monoxide are associated with AR and should prompt investigation. Radiography is not very sensitive. The histologic findings of AR include lymphocytic infiltrates into the perivascular and interstitial spaces; AR is graded according to histologic findings [100].

The initial treatment of AR in lung transplant recipients is similar to other organs with the use of high-dose corticosteroids; if they are not successful, anti–T-cell antibody therapy are the second line for steroid-resistant cases. Many recipients initially respond to the steroid pulse therapy, yet it may not completely clear their AR, and secondary episodes are common, and so additional therapy may be required. For that reason, surveillance bronchoscopy with transbronchial biopsies and BAL are common after initial treatment [99].

CR in lung transplant recipients is extremely common, affecting up to 40% of recipients at 2 years posttransplant and up to 70% of recipients after 5 years [101]. The mean time to diagnosis of graft dysfunction posttransplant is 16 to 20 months. A definitive histologic diagnosis of early bronchiolitis obliterans may be difficult to obtain, and so a high degree of clinical suspicion must be maintained. Radiography, again, is
not specific. Typical presenting symptoms are cough, progressive dyspnea, and loss of exercise tolerance. There are myriad of therapeutic modalities that have been attempted for recipients with bronchiolitis obliterans, but with little success. Increases in immunosuppression, antilymphocyte antibody therapy, and inhaled cyclosporine have all been tried. Ultimately, the progress of bronchiolitis obliterans is inexorable, with continued loss of graft function and subsequent death. A lung retransplantation is the only viable option [99]. Chapter 59 is devoted to lung transplantation.
SUMMARY

For more than half a century, substantial advances in the field of solid-organ transplantation have propelled the clinical practice from an experimental to a standardized and routine stage. Dramatic improvements in surgical techniques, immunosuppressive therapy, and medical/critical care have made it possible to increase the pool of potential recipients and now include those who would have been considered too sick or with too many comorbidities even a few years ago. However, despite this progress, until medical science is able to develop immunosuppressive drugs and regimens without side effects, or achieve routine tolerance induction, the predominant challenges in transplantation will remain the prevention, diagnosis, and treatment of GvHD, infection, malignancy, and rejection. These clinical problems have, however, improved in the nearly six decades since the first successful kidney transplant was performed; but they may become more complex throughout the 21st century as we now transplant many more complicated patients.

Section 7

RHEUMATOLOGIC, IMMUNOLOGIC, AND DERMATOLOGIC DISEASES IN THE INTENSIVE CARE UNIT
NANCY Y.N. LIU
Patients with established rheumatologic diseases are rarely admitted to the intensive care unit (ICU) because of their inflammatory joint disease. However, because many of these diseases include systemic involvement, organ system failure and complications of therapy are common reasons for ICU admission. Other musculoskeletal problems frequently encountered in the intensive care setting include (a) patients whose underlying rheumatic diseases may pose certain problems in the planning and execution of some critical care procedures, such as endotracheal intubation, or (b) patients for whom acute rheumatic syndromes develop during their hospitalization.

**ACUTE RHEUMATIC DISEASES IN THE INTENSIVE CARE SETTING**

Several acute musculoskeletal disorders occur with increasing frequency among selected hospitalized patients, including those in the ICU. The most common is crystal-induced arthritis because of monosodium urate, calcium pyrophosphate dihydrate (CPPD), basic calcium phosphate (BCP)-hydroxyapatite, or calcium oxalate crystals. Two other acute arthritides include septic arthritis from bacteremia and spontaneous hemarthrosis because of complications from anticoagulation therapy or bleeding diathesis.

**Gout**

**Pathogenesis**
Gout is characterized by initial and intermittent attacks of mono- or polyarticular arthritis in the setting of prolonged hyperuricemia. Over many years, attacks become more frequent, and chronic arthropathy may develop. Acute gout is triggered by precipitation or shedding of monosodium urate crystals in the joint space or nearby soft tissues, provoking an intense inflammatory reaction. Regardless of a primary or secondary etiology of hyperuricemia, marked fluctuations of serum urate levels increase the risk of acute gout.

Although the specific triggering event that initiates an isolated attack may be difficult to define, many factors cause serum urate fluctuations and result in an increased incidence of secondary gout among ICU patients. A reduction of glomerular filtration rate from either intrinsic renal disease or decreased effective arteriolar blood volume will result in reduced filtered load of urate, hyperuricemia, and an increased risk of gout. In addition, a reduction of effective arteriolar blood volume results in enhanced tubular reabsorption of urate. Because organic acids such as lactic acid, β-hydroxybutyric acid, and acetoacetic acid may competitively inhibit the renal tubular secretion of uric acid, conditions in which these acids accumulate will also lead to hyperuricemia. Mechanisms of hyperlacticacidemia among the critically ill patient are multiple.

Drug-induced hyperuricemia is a common cause of gout in both hospitalized and nonhospitalized patients. Diuretic therapy decreases effective arteriolar blood volume and also may directly inhibit renal tubular secretion of uric acid. Although thiazide diuretics are the most commonly implicated cause of hyperuricemia and gout, other diuretics including furosemide, acetazolamide, ethacrynic acid, and diazoxide are also potential culprits. Furosemide and diazoxide may also induce hyperlacticacidemia.

In addition to diuretics, other drugs associated with hyperuricemia include low-dose salicylates (less than 2.0 g per day), pyrazinamide, levodopa, α-methyldopa, and cyclosporine. Because of the uricosuric effect of radiocontrast media, a contrast study might precipitate an attack of acute gout. Finally, a hyperuricemic patient who undergoes any surgical procedure is at risk for postoperative gout.

Clinical Features

Gout is easily identifiable and treatable. Classically, the patient with acute gout complains of sudden onset of an exquisitely painful joint that involves one or more sites in an asymmetric pattern. The attack is sometimes accompanied by low-grade fever, particularly in a polyarticular presentation. The great toe is involved in more than 50% of the initial acute attacks and in 90% of acute attacks at some time in the course of the disease. Other common sites of involvement in order of
observed frequency include insteps, ankles, knees, wrists, fingers, and elbows. Periarticular sites of urate deposition in bursae, tendons, and soft tissues may be similarly inflamed during an acute attack. On examination, the involved area is erythematous, swollen, warm, and exquisitely painful on palpation, sometimes with joint motion. The overlying erythema and edema often extend beyond the joint capsule and can mimic cellulitis or bursitis.

The presence of lymphangitis or lymphadenopathy and the absence of pain on joint motion are more consistent with cellulitis. Bursitis can be distinguished from true arthritis because full joint extension is preserved in bursitis, and the region of erythema is not within the borders of the joint compartment. If clinical suspicion of joint infection is low, then diagnostic arthrocentesis should be avoided until a therapeutic trial of appropriate antibiotics for cellulitis has been completed. Otherwise, there may be a risk of introducing organisms into a sterile joint. However, if motion is restricted or if radiography suggests an effusion, a diagnostic arthrocentesis should be performed before the institution of any therapy.

The diagnosis of gout is confirmed when aspirated synovial fluid or soft tissue site reveals negatively birefringent monosodium urate crystals within polymorphonuclear neutrophils (PMNs) under polarizing light microscopy. Gouty synovial fluid is inflammatory, with more than 2,000 leukocytes per μL, occasionally as high as 100,000 per μL, and PMNs predominate in the cell differential. Because gout and septic arthritis have similar clinical features and can coexist, aspirated synovial fluid should always have a Gram stain for microorganisms and bacterial culture performed. Elevations of the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and peripheral leukocytosis cannot distinguish gout from other inflammatory states. Serum urate may be normal during an acute attack, whereas an elevated level does not confirm the diagnosis without crystal identification.

Therapy

Once the diagnosis of acute gout is established, the immediate aim of therapy is to terminate the attack by interruption of the inflammatory response. Long-term management (e.g., prevention of recurrent attacks, sequelae of tophaceous disease, or renal stones) need not be initiated in the ICU setting. In fact, the initiation or discontinuation of any drugs that alter urate levels (i.e., allopurinol, febuxostat, probenecid, or lesinurad) may prolong the acute attack without preventing it. Asymptomatic hyperuricemia should not be treated.
**Corticosteroids** Systemic and intra-articular steroids are effective for the treatment of gout. Intravenous (IV) methylprednisolone (0.5 to 2 mg per kg IV daily for 3 to 5 days depending on severity and number of joints involved) is the preferred agent in critically ill patients [1]. Oral prednisone may also be effective in doses of 0.5 mg per kg initially and tapered over 7 to 14 days, with decrements of 10 mg every 2 days [1]. Potential complications of steroid treatment include hyperglycemia, fluid retention secondary to mineralocorticoid effects, and hypothalamic–pituitary–adrenal suppression. Intra-articular corticosteroid injection is an excellent choice for acute gouty arthritis if few joints are involved because systemic side effects are avoided. Steroid injection provides rapid resolution of symptoms, usually within 12 to 24 hours, but if infection is suspected, corticosteroid injection should be delayed until culture results are available. Intra-articular corticosteroids are quite effective in small joints if performed by physicians skilled in these injections. Dosing ranges from 10 to 60 mg methylprednisolone or equivalent triamcinolone, depending on the size of the joint involved.

**Colchicine** Colchicine is one of the established treatments for gout. Its main mechanism of action involves formation of a reversible complex with the tubulin subunit of microtubules, leading to reduced activation and migration of PMNs. Oral colchicine is absorbed in the small intestine and excreted in the bile and urine, reaching a peak serum level in 2 hours. Gastrointestinal side effects, most notably diarrhea, occur among up to 80% of patients, resulting in electrolyte imbalances and fluid losses. In the critically ill patient, oral colchicine may not be feasible and is potentially toxic. Renal and hepatic insufficiencies are risk factors for colchicine-related neuromyopathy and bone marrow suppression. In addition, potential drug–drug interactions, including macrolide antibiotics, HMG-CoA reductase inhibitors, fibrin acid derivatives, verapamil and diltiazem, and cyclosporine, may potentiate colchicine toxicities.

Current recommendations for treatment of acute gout with lower dose colchicine (1.2 mg orally followed in 1 hour by another 0.6 mg orally) as opposed to traditional oral loading of colchicine (1.2 mg orally followed by 0.6 mg every hour for 6 hours) are preferred, with fewer toxicities [2]. In addition, the gastrointestinal side effects are significantly reduced with the lower dose regimen. Thus, if an ICU patient with an acute onset of gout has normal renal and hepatic function and is able to take oral colchicine, the low-dose regimen is a reasonable choice. However, if there is renal insufficiency, dose adjustment is necessary and colchicine is probably best avoided if creatinine clearance is less than 10 mL per minute. A more appropriate use of oral colchicine is for the prevention of subsequent attacks once the acute attack is treated. Dosages of 0.6 mg
orally once or twice a day have been effective (again dose adjustment is necessary based on GFR) [3]. The most common side effects include nausea, diarrhea, and proximal myopathy with elevated creatinine kinase levels. The risk of myotoxicity correlates with a creatinine clearance of less than 50 mL per minute.

**Nonsteroidal Anti-inflammatory Drugs** Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective for the treatment of acute gout. However, the mechanism of action involves prostaglandin inhibition, which can interfere with gastric mucosal integrity and worsen renal function by reducing renal perfusion in the setting of volume contraction. NSAIDs may also cause other side effects, including decreased coronary flow and mental status changes. Although the cyclooxygenase-2 inhibitor agents offer the possibility of fewer adverse events, their safety profile is based on outpatient experience. Serious adverse effects with these newer agents have been reported. Given the fact that many patients in the ICU have some degree of renal disease and are at risk for gastrointestinal bleeding, NSAIDs are rarely a first-line agent in the treatment of gout in the ICU.

**Other Microcrystalline Arthropathies**

Although gout is the best-defined and most common crystalline arthropathy, several other crystalline-induced syndromes may mimic gout and cause potential diagnostic confusion. These include CPPD, BCP-hydroxyapatite, or calcium oxalate crystals.

**Pathogenesis**

The pathophysiology of these entities appears to be similar to that of gouty arthritis, involving a complex series of biochemical reactions that lead to an inflammatory response within the involved joint or periarticular region.

The acute, self-limited form of CPPD deposition (also known as *pseudogout*) may be precipitated by surgery of any type, and is related to downward fluxes of serum calcium levels that lead to crystal shedding into intra-articular spaces. Attacks commonly occur several days postoperatively and often involve the knee or wrist. Severe medical illnesses, such as ischemic heart disease, cerebral infarction, and thrombophlebitis, may also provoke attacks of CPPD arthritis.

Patients on chronic intermittent peritoneal dialysis have a high incidence of acute arthritis that is secondary to CPPD or BCP-hydroxyapatite deposition in articular cartilage. In contrast, chronic hemodialysis patients are at risk for acute arthritis from calcium oxalate crystals.
Clinical Features

Clinically, each of the above crystalline arthropathies is clinically indistinguishable from acute gout. The presence of radiographic calcification in hyaline or articular cartilage of the involved joint (i.e., chondrocalcinosis) suggests the diagnosis of pseudogout, but the diagnosis is confirmed by visualizing weakly positively birefringent, rhomboid-shaped CPPD crystals within synovial fluid PMNs under polarizing microscopy. Calcium oxalate crystals, likewise, are positively birefringent, but they are pleomorphic, bipyramidal, or rod-like in shape. Smaller BCP-hydroxyapatite crystals, however, are not visible under polarizing microscopy, and a presumptive diagnosis is made given the clinical setting, the exclusion of other diagnoses, and the occasional presence of periarticular, amorphous calcifications on radiographs.

Therapy

Therapeutic options are limited in the ICU patient if NSAIDs are contraindicated. Isolated joints can be aspirated and injected with corticosteroids once infection is excluded. Alternatively, a regimen of tapering corticosteroids similar to acute gout is effective. Pseudogout may also respond dramatically to colchicine in dosing similar to gout. Low-dose colchicine is also used to prevent recurrent attacks for patients who have frequent events.

Septic Arthritis

Joint infection is the most critical diagnosis to establish and treat in any ICU patient who develops acute mono- or oligoarthritis. A delay in the diagnosis and treatment of septic arthritis may lead to destruction of articular cartilage and loss of joint function. Furthermore, a diagnosis of septic arthritis may help identify and initiate early treatment of the source of septicemia, such as endocarditis (see Chapter 78).

Pathogenesis

Risk factors for development of septic arthritis include diabetes mellitus, age over 80, skin infections, rheumatoid arthritis (RA), IV drug abuse, alcoholism, recent joint surgery, low socioeconomic status, and prosthetic joints [4]. In addition, patients in the ICU often have multiple invasive procedures, indwelling lines, or catheters that are potential portals of
infection. Acute septic arthritis usually develops from hematogenous seeding from another site of infection. Direct inoculation or local extension from adjacent soft tissue infection or osteomyelitis is less common. Prosthetic joints or damaged joints from rheumatoid or osteoarthritis are particularly susceptible to hematogenous seeding. Once an infection is established within a joint, a complex cascade of physiologic responses occurs that leads to a severe inflammatory reaction, with subsequent cartilage degradation and bone destruction. The rapidity and severity of this process depend on the virulence of the organism and the length of delay before appropriate antibiotics are started.

**Clinical Features**

Clinically, septic arthritis may be indistinguishable from crystalline arthritis or other inflammatory joint diseases. The presentation is often acute and monoarticular, with physical findings of warmth, swelling, tenderness, erythema within the confines of the joint margins, and markedly limited joint motion. The knee, hip, shoulder, elbow, and ankle are the most frequently involved joints. Atypical joints such as the sternoclavicular or sacroiliac joints, and the symphysis pubis are common sites of infection in younger patients, or those with a history of IV drug use. Polyarticular infections occur in 20% of cases [4], particularly among patients with RA. Fever is a variable finding and may be low grade.

High clinical suspicion remains essential to the diagnosis of septic arthritis. Unless physical examination indicates extra-articular features (e.g., cellulitis), any ICU patient with an acutely swollen, painful joint needs a diagnostic arthrocentesis to exclude infection. In the case of suspected cellulitis, appropriate antibiotics should be administered and arthrocentesis performed only if symptoms or findings do not improve within 48 hours. The diagnosis of septic arthritis is supported by an elevated white blood cell (WBC) count, ESR, and CRP, but these studies cannot reliably differentiate infection from other inflammatory processes. Conversely, the absence of fever or normal ESR or CRP cannot exclude septic arthritis. Synovial fluid analysis can confirm septic arthritis and identify organisms on Gram’s stain or in culture. The fluid should be transferred immediately to the laboratory, both anaerobic and aerobic cultures should be ordered routinely, and special requests for fungus or other organisms that require a special growth medium (e.g., *Neisseria gonorrhoeae*) are ordered if clinically indicated. In addition, synovial fluid analysis for WBC with differential and microscopic examination for crystals may support a diagnosis of infection before microbiology results are available. Although leukocyte counts under 20,000 per μL have been associated with septic arthritis, the WBC generally exceeds 50,000 per μL
and on occasion may be as high as 200,000 per μL, with a marked PMN predominance. A meta-analysis of various laboratory studies in septic arthritis suggests that the likelihood ratio of septic arthritis increases incrementally with higher synovial leukocyte counts [5]. However, because septic arthritis has been associated with WBC as low as 2,000 to 50,000 per μL, the absolute number cannot differentiate septic arthritis from other inflammatory states such as rheumatoid, psoriatic, or crystalline arthritis.

Although initial radiographs of the infected joint are often normal, baseline x-rays are useful to identify preexisting joint abnormalities and for comparison to identify subsequent damage. Magnetic resonance imaging (MRI) may be helpful to evaluate joints that are difficult to assess clinically (i.e., spine, sacroiliac, or hip) for underlying osteomyelitis and sinus tracts. Classic late radiographic findings include juxta-articular osteopenia, joint-space narrowing, or subchondral bone loss.

Therapy

Treatment of septic arthritis requires adequate drainage in addition to appropriate antibiotics. _N. gonorrhoeae_ is the most common cause of septic arthritis in patients under the age of 30, but overall, _Staphylococcus aureus_, including methicillin-resistant _S. aureus_ (MRSA), is the most common organism in the immunocompetent patient, followed in frequency by _Streptococcal_ species. Gram-negative and anaerobic organisms occur less frequently, but must be suspected in patients at risk (elderly, immunocompromised, recent hospitalization or surgery, prior antibiotics, and possible urogenital or abdominal infections) [4]. For the critically ill patient with multiple risk factors, broad-spectrum antibiotic coverage against _Staphylococcus_ and _Streptococcus_, Gram-negative bacteria, and _Pseudomonas_ should be initiated until culture results are available. Fungal or mycobacterial septic arthritis is often subacute or chronic, but should be considered in patients failing broad-spectrum antibiotics. _Candida_ organisms have caused acute arthritis and the Gram stain or fungal preparation may be positive before cultures are available. The duration of antibiotic therapy varies according to the clinical situation, but antibiotics should be continued intravenously for at least 2 weeks. Further route and duration of therapy depend on the specific type and sensitivity of the identified organism and the patient’s clinical response. The length of treatment is usually at least 4 weeks for nongonococcal septic arthritis. Please refer to Chapter 73 for appropriate antibiotic treatment for presumptive or identified infectious organisms.

Drainage of the infected joint with either serial percutaneous needle
aspiration or surgical intervention is also crucial. Because there are no prospective studies comparing these options, controversy exists regarding the optimal approach. The physical removal of inflammatory cells, cellular debris, lysosomal enzymes, and bacterial by-products reduces the potential damage to the joint. Prosthetic joints and other native joints such as hip, shoulder, wrist, finger, sacroiliac, or sternoclavicular joints require immediate surgical intervention, whereas native septic knees may respond to serial percutaneous needle aspiration. Arthroscopy or arthrotomy has the advantage of more complete debridement of fibrin, infected synovium, and loculations. However, percutaneous drainage may be the only option for a critically ill patient who is too unstable for surgery. Indications for surgical intervention include initial delay in diagnosis, established joint damage from RA or osteoarthritis, failure to sterilize the joint fluid after 3 to 5 days of antibiotics, difficult percutaneous aspirations because of loculations, or infection with Gram-negative bacterium. Thus, the ideal approach is to consult both an orthopedic surgeon and a rheumatologist at the time of diagnosis to decide on optimal management.

The infected joint should be immobilized in functional position in the first few days. Once antibiotics are given and drainage has been performed, early physical therapy with passive range of motion and graduation to active range of motion will improve outcomes.

Because septic arthritis usually occurs as a consequence of bacteremia from a distant primary source of infection, investigation for these sites must be pursued. Unless an obvious site of local inoculation is present, cultures from blood, urine, sputum, indwelling lines, and catheters should be obtained before the institution of antibiotics. In addition, imaging studies such as echocardiography, computed tomography (CT), or gallium scanning may locate the source of occult infection.

**Septic Arthritis of the Prosthetic Joint**

Although rates of prosthetic joint infections (PJIs) are generally quite low, 0.8% to 1.9% and 0.3% to 1.7% for knees and hips, respectively [6], RA patients have an increased risk of developing infected prosthetic joints. Risk factors are similar for native joint septic arthritis discussed previously and also include prior infection of a prosthetic joint at the same site or revision arthroplasty. Early infection, usually within 3 months of surgery, is usually due to *S. aureus* or more virulent organisms from direct inoculation at the time of surgery; chronic infections with less
aggressive bacterium including coagulase-negative *Staphylococci* occur often months to years after the replacement. Bacteremia with seeding of a prosthetic joint can occur anytime. Causative organisms for PJI are predominantly Gram-positive cocci (65%); aerobic Gram-negative bacilli and anaerobes contribute 10%, whereas 20% are polymicrobial infections [6].

Clinical features of acute PJI include localized pain, fever (occurring in <50%), and elevation of ESR, whereas more chronic infections may present with only pain and loosening of hardware on radiograph. CRP elevation of more than 5 mg per L has a sensitivity of 95% and specificity of 62% in the diagnosis of PJI [7]. Plain radiographs cannot distinguish aseptic periprosthetic loosening from infection. CT and magnetic imaging may be distorted by ferromagnetic prostheses. Synovial fluid studies are as useful for the diagnosis of PJI as they are for native joint infections. A synovial fluid WBC more than 1,700 cells per μL from the prosthetic knee joint or more than 4,200 cells per μL from the prosthetic hip joint with predominantly PMNs is enough to suggest infection [6]. If aspiration is not done before surgery, then intraoperative sampling of multiple periprosthetic tissue sites will increase the yield of an organism. Culture of the removed prosthesis may also provide additional microbial information.

Treatment of suspected PJI should initially cover both Gram-negative and Gram-positive organisms with a regimen such as vancomycin and an aminoglycoside until microbiology results and antibiotic sensitivities are available (see Chapter 73). Infectious disease consultation will help guide therapy.

Antibiotic therapy alone without surgical intervention is rarely successful. If the patient is a surgical candidate, options include: (1) resection arthroplasty, (2) one- or two-stage surgery with prosthesis removal and reimplantation, or (3) surgical debridement with retention of prosthesis with or without long-term oral antibiotic suppression. The first option is rarely performed unless the patient has failed previous surgical attempts at eradicating the infection or is likely to have minimal functional improvement after replacement. Chronic PJI requires resection arthroplasty with one- or two-stage exchanges. The latter usually entails removal of the infected prosthesis, treatment with antibiotics with or without an antibiotic-loaded spacer for a period of 6 to 12 weeks, and then subsequent reimplantation. Debridement with retention of the infected prosthesis is an option only if (i) age of the prosthesis is less than 3 months; (ii) symptoms have been present for less than 3 weeks; (iii) absence of sinus tract communicating with joint space; (iv) no radiographic evidence of prosthetic loosening; (v) infection not involving *S. aureus, Pseudomonas aeruginosa*, enterococcus, fungal- or multidrug-resistant organisms; and (vi) absence of comorbidities such as
diabetes and RA [8]. Prolonged oral antibiotics (3 months for hips and 6 months for knees) are recommended in patients treated with debridement with implant retention [6].

**Hemarthrosis**

In the absence of an underlying inherited disorder of coagulation, hemarthrosis in the intensive care setting is most likely a complication of anticoagulation therapy, most frequently described in patients receiving an oral anticoagulant. Because hemarthrosis may occur spontaneously in an anticoagulated patient, a history of trauma is often absent. Clinically, a patient develops a monoarticular, painful, swollen, warm, and tense effusion. Prolongation of coagulation parameters suggests the diagnosis, but diagnostic arthrocentesis is essential to confirm the diagnosis of hemarthrosis and exclude septic arthritis, crystalline disease, or other causes. When performed aseptically and carefully, arthrocentesis is safe and free of significant long-term morbidity. It is unnecessary to reverse the anticoagulant state prior to arthrocentesis.

A precise definition of hemarthrosis has not been established, but the diagnosis is suggested by a synovial fluid hematocrit exceeding 3%. Causes of hemarthrosis other than anticoagulation include trauma (especially with intra-articular fracture), blood dyscrasias, Charcot joint, synovial tumors such as pigmented villonodular synovitis, or other primary or metastatic neoplasms, myeloproliferative disease, CPPD arthropathy, septic arthritis, sickle cell trait or disease, or scurvy.

Despite the fact that hemophiliac patients with repeated hemarthrosis have significant joint abnormalities, an isolated episode of spontaneous hemarthrosis has a benign prognosis. Treatment of hemarthrosis from hemophilia or other bleeding diathesis is discussed elsewhere (see Chapters 88 and 89). Management of spontaneous hemarthrosis from anticoagulation consists of immobilization, analgesia, and, if possible, temporarily reducing or correcting clotting parameters with fresh frozen plasma or reversal agents when the patient is not at high risk of thrombotic complications. If the patient is at high risk (i.e., prosthetic valve), allowing the international normalized ratio (INR) to drift toward the lower therapeutic range is one option. Arthrocentesis may reduce the pressure of joint distension.
ASPECTS OF RHEUMATIC DISEASES COMPLICATING INTENSIVE CARE PROCEDURES

Difficult endotracheal intubations may be encountered among patients with RA, juvenile idiopathic arthritis (JIA), ankylosing spondylitis (AS), or systemic sclerosis (SSc). Involvement of the cervical spine, temporomandibular or cricoarytenoid joints, or oral aperture may limit adequate positioning, visualization, or successful endotracheal intubation with conventional direct laryngoscopy. Advanced airway techniques including fiberoptic intubation, video laryngoscopy, and nasotracheal intubation enable safe airway placement for most patients with difficult airways (see Chapter 8). Laryngeal mask airway is a possible rescue measure for patients who cannot be intubated but can be ventilated and is a good alternative to bag mask ventilation. A surgical airway, cricothyroidotomy or tracheostomy, is required in emergent situations when safe intubation is not possible and the patient cannot be adequately ventilated (see Chapters 8 and 9).

The prevalence of atlantoaxial instability among RA patients is estimated to be 23% to 60% depending on the subpopulation studied and is associated with longer duration and greater severity of disease. This instability also occurs among certain subgroups including patients with JIA and AS. Although the majority of patients with cervical spine involvement are asymptomatic, forced manipulation of the neck (e.g., during intubation, endotracheal suctioning, nasogastric tube placement, bronchoscopy, or endoscopy) may precipitate symptoms and signs of spinal cord compression.

Cervical instability and dislocations most commonly occur at the atlantoaxial (first and second cervical vertebrae) junction because of laxity or erosion of the transverse ligament caused by synovitis. Subsequently, the odontoid (superior peg of the axis) moves more freely and can protrude posteriorly, particularly during neck flexion, and compress the spinal cord, lower medulla, or vertebrobasilar arteries. Fracture or erosive destruction of the odontoid may allow the atlas to slide posteriorly on the axis, a process termed posterior atlantoaxial subluxation. Destruction of the lateral atlantoaxial joints and of the bones
of the foramen magnum may allow the axis to sublux cephalad, so-called vertical subluxation. Symptoms suggestive of cervical myelopathy include Lhermitte’s sign, neck pain radiating up to the occiput, paresthesias in the hands or feet, loss of arm or leg strength, and urinary incontinence or retention.

Atlantoaxial instability is identified with lateral cervical spine radiographs in flexed and extended views. The normal distance between the odontoid process and the Arch of the Atlantis is less than 4 mm. If this distance is exceeded, care should be taken to avoid sudden or forced neck flexion during any intensive care procedure. A soft cervical collar to maintain the neck in slight extension helps prevent sudden forced flexion and is a reminder to all caregivers that any neck manipulation should proceed with caution. Open-mouth posterior-to-anterior views will exclude odontoid fracture and severe subluxation, but MRI scanning is the best imaging procedure to exclude cord compression.

Among patients with AS with multilevel cervical fusion, large anterior cervical osteophytes can prevent adequate visualization of the larynx or successful endotracheal intubation using standard techniques. Fixed cervical flexion deformities can hinder appropriate neck positioning for intubation. The ankylosed spine is often osteoporotic and brittle. Minor forces in flexing or extending the neck can result in inadvertent fracture. Thus, plain radiographic imaging with lateral views before any procedure can help establish potential barriers to endotracheal intubation and the need for advanced intubation techniques.

Patients with JIA (and less commonly RA) may have micrognathia because of temporomandibular joint disease that restricts lower jaw motion and limits access to the oropharynx. Micognathia may also cause upper respiratory tract obstruction and sleep apnea, both of which occur more commonly in patients with JIA. In contrast, patients with SSc may have facial tissue fibrosis and atrophy that reduce the oral aperture and make orotracheal intubation difficult or impossible. In these situations, early awareness of the need for nasotracheal intubation or other advanced airway techniques will prevent potential complications in routine or emergency endotracheal intubation.

Nearly 50% to 75% of patients with long-standing RA have involvement of the cricoarytenoid joints on CT scans, but only half have symptoms. These synovial joints allow adduction and abduction of the vocal cords. Symptoms of cricoarytenoid involvement include throat pain, sensation of a foreign object in the throat, odynophagia, dysphagia, hoarseness, shortness of breath, and stridor. As a result of acute or chronic inflammation, the vocal cords may become fixed in adduction, resulting in upper airway obstruction and respiratory failure. The diagnosis may be distinguished from recurrent laryngeal nerve paralysis, tumor, and thyroiditis by visualizing the vocal cords by either direct laryngoscopy or
fiberoptic nasopharyngoscopy. For the patient with chronically restricted motion of the cricoarytenoid joints, a superimposed insult, like an upper respiratory tract infection or trauma from intubation, may cause laryngospasm or soft tissue swelling with resultant airway obstruction. Treatment of life-threatening airway obstruction includes establishing an airway by cricothyroidotomy or tracheostomy, administration of high-dose systemic corticosteroids, systemic antirheumatic therapy, or topical aerosolized corticosteroids.
RHEUMATOID ARTHRITIS

RA is a chronic, autoimmune, inflammatory disorder that affects synovial joints and extra-articular organ systems. In the patients with established RA, reasons for admission to the ICU may include airway obstruction because of cricoarytenoid arthritis or atlantoaxial subluxation (discussed previously); septic arthritis; respiratory distress from large pleural effusions or parenchymal lung disease; mononeuritis, or cardiac dysfunction because of pericardial, myocardial, or endocardial involvement; necrotizing vasculitis. The approach to the RA patient in the ICU includes knowledge of the diverse complications of rheumatoid disease and the potential toxicities of RA medications including NSAIDs, corticosteroids, nonbiologic disease-modifying agents, and the newer biologic agents. In addition, RA may be among the differential diagnoses for an acutely ill ICU patient with various organ system involvement, and thus consultation with a rheumatologist is most helpful.

Pathogenesis

RA is characterized by chronic synovial inflammation with subsequent articular cartilage and bone destruction in a genetically susceptible host. The initial triggering antigen, whether exogenous or self, has not been identified, but the initial activation of innate immunity and the subsequent stimulation of T cells initiate the process of recruitment of other cells to the synovium, including macrophages, neutrophils, and B cells. Fibroblast-like and macrophage-like synovial cells perpetuate synovial inflammation through elaboration of cytokines that have paracrine and autocrine activities. In addition to cytokines, the products of several cell types also induce adhesion molecules and stimulate angiogenesis. Activated synovial cells also release metalloproteinases and other enzymes responsible for degradation of articular cartilage and erosion of bone. The disease is characterized by the presence of rheumatoid factor (RF) and anti-citrullinated protein antibodies (ACPA). This latter antibody is more specific for RA and higher titers are associated with more severe disease and some extra-articular organ involvement.

Joint Infections Complicating Rheumatoid Arthritis

One indication for admission of the RA patient to an ICU is sepsis, particularly involving joints. RA patients are more susceptible to developing septic arthritis, often polyarticular and more severe than in
patients without RA. A variety of factors, including immunosuppressive drugs, general debility, immobility, and cutaneous ulcers predispose the RA patient to developing bacterial infections in other sites, which hematogenously seed inflamed rheumatoid joints. Normal protective mechanisms, PMN leukocyte bacterial killing, PMN chemotaxis, and complement and serum bactericidal activity of the rheumatoid joint are all decreased. Although joint sepsis after arthrocentesis or intra-articular steroid injection is a rare complication, infection has been reported in this context and may be more resistant to treatment.

A delay in diagnosing joint sepsis for RA patients may also contribute to their increased morbidity and mortality. Other factors include: (1) masking of joint pain and inflammation by NSAIDs, corticosteroids, and immunosuppressive agents; (2) generalized debility and malnutrition; and (3) attributing the joint inflammation to RA rather than infection by the patient or physician. Failure to recognize septic arthritis complicating RA may have disastrous effects. When a single or few joints are more inflamed more than others in a rheumatoid patient, joint sepsis should be excluded by arthrocentesis, Gram’s stain, and cultures of synovial fluid, blood, and other appropriate sites guided by the patient’s signs and symptoms. Inspection of the skin for a possible portal of bacterial entry and a thorough general examination are of utmost importance.

The microbiology of septic arthritis complicating RA includes a wide range of organisms, but in approximately 80% of cases, the organism is *S. aureus*, with an increasing proportion of MRSA infections. Streptococcal species are also common pathogens. Gram-negative organisms (*P. aeruginosa, Escherichia coli, Proteus mirabilis*, and others), anaerobes, fungi, mycobacterium, and polymicrobial infection have all been reported as causes of septic arthritis of the rheumatoid joint.

Management of septic arthritis for a rheumatoid patient is identical to that of patients without RA. However, the septic rheumatoid joint more frequently fails percutaneous needle aspiration. Early surgical drainage with synovectomy may be the preferred treatment because there is more proliferative synovitis and an increased tendency for loculations to develop.

**Pulmonary Involvement in Rheumatoid Arthritis**

The respiratory system of the patient with RA can be involved in numerous ways, including upper airway, bronchi, pleura, parenchyma, vasculature, and diaphragmatic muscles. Pulmonary infections are
common, particularly among patients with poor mucociliary clearance, with ineffective cough, on immunosuppressive therapy, or with associated Sjögren syndrome. Table 66.1 summarizes respiratory tract involvement in RA and other connective tissue disorders. In addition, certain antirheumatic drugs are associated with pulmonary toxicities. Angioedema and bronchospasm induced or aggravated by aspirin or other NSAIDs are most common, followed by hypersensitivity pneumonitis from methotrexate, sulfasalazine, the newer biologics, or interstitial fibrosis from methotrexate.

**Pleural Disease**

Pleuritis and interstitial disease are the most common pulmonary manifestations of RA, and the former is most common in a subset of male patients who are seropositive and have nodules. Although involvement may be asymptomatic, acute febrile pleurisy or large pleural effusions impairing respiratory function may occur and result in ICU admission. The differential diagnoses of the pleural effusions include malignancy, pulmonary infarction, viral or bacterial infection, tuberculosis, and empyema. Infectious empyema occurs with increased frequency in patients with preexisting rheumatoid pleural effusions and should be suspected in debilitated, anemic, or hypoproteinemic patients who have been treated with corticosteroids and have persistent fever and pleural effusions. In patients on anti–tumor necrosis factor α (anti-TNFα) therapies, reactivation of (or new infection with) tuberculosis is a major concern and needs to be excluded with pleural biopsy.

Pleural effusions and sterile empyemas associated with RA are exudative and have characteristic features: elevated lactic dehydrogenase (often >700 International Units per L), total protein (>4 g per dL), low glucose (<40 mg per dL), and pH <7.2. Other characteristics include clear yellow to green-yellow appearance, WBC count of 100 to 7,000 cells per μL (predominantly lymphocytes), reduced complement levels, cholesterol crystals, and immune complexes [9]. Chylous effusions may occur if necrotic subpleural nodules rupture into the pleural space.

Once infections including tuberculosis and malignancy are excluded, symptomatic pleural effusions are managed with NSAIDs and thoracentesis. In recurrent pleuritis or sterile empyema, intrapleural
corticosteroids, systemic corticosteroids in moderate doses, and additional disease-modifying agents are recommended. Rarely, surgical pleurodesis or decortication is required if chronic adhesive fibrothorax develops. There are no prospective trials to evaluate the efficacy of many of these recommendations [9]. High-dose corticosteroid therapy may not be effective and carries an increased risk of empyema formation.

**Lung Disease**

RA-associated interstitial lung disease (RA-ILD) occurs among 40% to 60% of patients depending on the subpopulations studied and screening tests used to make the diagnosis. In a review of rheumatoid lung-associated mortality using the US National Center for Health Statistics, clinically significant RA-ILD was 10%; the incidence of mortality was 28.3% for women and 12.5% for men from 1988 to 2004 [10]. In a large UK study, review of RA patients with ILD was estimated to be around 5% to 6%. Males and females were nearly equally affected. Risk factors for poor prognosis included high-titer RF and ACPA, smoking in males, and extent of lung involvement on high-resolution CT (HRCT) scans [11]. Thus, after infection, pulmonary disease is the second most common cause of mortality among RA patients. Pathologically, usual interstitial pneumonia (UIP) is more common (up to 60%), followed by nonspecific interstitial pneumonitis (NSIP). Cryptogenic organizing pneumonia (OP) and acute interstitial pneumonia are less common, whereas lymphocytic interstitial pneumonitis (LIP) and desquamative interstitial pneumonia are rare in RA.

Symptoms include dyspnea on exertion, cough, and chest discomfort. Physical and laboratory findings include dry crackles, diminished diffusion capacity, and restrictive physiology, as well as desaturation with exercise. Chest radiographs may show an interstitial pattern, but HRCT is the most sensitive test in diagnosing UIP and NSIP, with up to 70% correlation with histopathologic findings. Fibrotic changes with honeycombing and traction bronchiectasis are more suggestive of UIP, whereas alveolar infiltrates and ground glass changes are more suggestive of NSIP, acute hemorrhage, or interstitial pneumonia. Bronchoalveolar lavage (BAL) is not particularly helpful except to rule out infection, hemorrhage, or malignancy, whereas thoracoscopy-guided lung biopsy provides the best pathologic material for diagnosis and may be needed when the diagnosis is unclear despite the above evaluations. Treatment of RA-ILD is extremely challenging because there are no randomized trials, and often therapies are extrapolated from idiopathic ILD or treatment for lung disease associated with connective tissue disease. Some patients may respond to corticosteroids alone, but the progressive nature of the disease may require treatment with cytotoxic agents, although it is
unclear which immunosuppressants are most effective [12]. In those patients with ground glass opacities on HRCT scanning, IV cyclophosphamide (IVCY) or mycophenolate mofetil (MMF) is frequently used, although no large controlled trial exists to support this approach. Case reports on the use of anti-TNF α medications are conflicting because there are case reports of these drugs being associated with exacerbation of RA-ILD.

Other less common manifestations of rheumatoid lung disease may require treatment in the ICU when patients develop respiratory distress. These include OP, obliterative bronchiolitis (OB), pulmonary vasculitis, spontaneous pneumothorax, and lung toxicities secondary to anti-rheumatic therapy. It is particularly important to distinguish OP from ILD and OB, and only lung biopsy will provide histologic distinction.

Obliterative alveolitis is often characterized by the abrupt onset of dyspnea and a dry cough with inspiratory crackles, sometimes with a mid-inspiratory squeak, a clear chest radiograph or finding of hyperinflation, irreversible airflow obstruction at low volumes on pulmonary function testing, mild-to-moderate arterial hypoxemia with a respiratory alkalosis, and progressive obliteration of small airways (1 to 6 mm in diameter) with constrictive bronchiolitis [13]. The prognosis is generally poor with a fairly rapid rate of progressive airflow obstruction. Despite the lack of adequate therapeutic trials, when patients present with rapidly progressive deterioration, recommendations based on expert opinion include bronchodilators, inhaled and oral corticosteroids (1 to 1.5 mg/kg/d). Macrolides, pulse IVCY, or etanercept (with methotrexate) may be considered as second-line therapies [13]. Progression to respiratory failure is common.

In contrast, patients with OP present with more systemic symptoms of fevers, malaise, weight loss, and dyspnea but are more responsive to corticosteroid therapy. Rarely, chronic vasculitis may involve pulmonary as well as bronchial arterioles and result in pulmonary hypertension and cor pulmonale. Therapy consists of corticosteroids in combination with cytotoxic agents (see Chapters 67 and 68).

Although pulmonary manifestations of RA are frequent, they are rarely the primary reason for admission to the ICU. Infectious pneumonia is particularly frequent and the major cause of mortality in rheumatoid patients. Since the development and widespread use of anti-TNFα medications, atypical infections and reactivation of tuberculosis have been of great concern. Drug-induced pneumonitis must also be excluded because many of the drugs for treatment of RA have pulmonary toxicities including methotrexate, leflunomide, sulfasalazine, and, less commonly, anti-TNFα, tocilizumab, and rituximab (RTX).

Rheumatoid Cardiac Involvement
RA may involve all structures of the heart as a result of granulomatous proliferation or vasculitis. Pericarditis, myocarditis, endocarditis (valvulitis), coronary arteritis, aortitis, and cardiac conduction abnormalities have all been reported. Cardiac involvement may be the principal reason for intensive care hospitalization, or may complicate the course of the rheumatoid patient hospitalized in the ICU for other medical or surgical problems.

Pericarditis, the most common of the rheumatoid cardiac manifestations (up to 30% by echocardiography but as high as 50% by autopsy studies), rarely causes clinical symptoms. However, constrictive pericarditis or a large pericardial effusion may result in cardiac tamponade. The pericardial fluid has the same characteristics as pleural fluid (see the section “Pulmonary Involvement in Rheumatoid Arthritis”). Pericarditis generally responds to the administration of moderate- to high-dose steroids (0.5 to 1 mg per kg), depending on severity of cardiac impairment. Corticosteroids alone are less likely to be effective in the setting of cardiac tamponade. Pericardiocentesis should be performed early when tamponade is suspected (see Chapter 17) or if there is a question of septic or suppurative pericarditis. Aspiration of pericardial fluid may temporarily improve cardiac function, but often the viscosity of the fluid, loculations, and thickness of the pericardium may necessitate pericardiectomy. In cases of symptomatic constrictive pericarditis, pericardiectomy is the only effective therapy.

The myocardium may be affected by granulomatous inflammation that results in heart failure or conduction system abnormalities. Although myocarditis is clinically rare, newer cardiac MRI with enhancement techniques suggests that myocardial fibrosis and inflammation exist in many asymptomatic RA patients. Arteritis may affect the coronary arteries or the aorta. For patients with active systemic vasculitis, coronary arteritis may be the cause of myocardial infarctions. Involvement of the aorta, either by rheumatoid granulomas or inflammation of the aortic vasa vasorum, may result in dilatation of the aortic root and aortic valvular insufficiency.

RA patients die prematurely from cardiovascular events that include (i) ischemic heart disease, often silent; (ii) congestive failure, often in the setting of preserved ejection fraction; and (iii) sudden death. When compared to non-RA patients, these increased cardiovascular complications and mortality (more than twice that of non-RA populations) are not explained by traditional risk factors alone. Other factors, including chronic inflammation, accelerated atherosclerosis,
various drugs used for treatment of RA that affect thrombotic or lipid profiles, and rarely coronary vasculitis, contribute to premature cardiac deaths. Thus, in the ICU setting, silent cardiovascular disease with atypical presentations must be considered for rheumatoid patients.

**Rheumatoid Vasculitis**

Rheumatoid vasculitis (RV) is a panarteritis involving typically medium size to small arterioles and postcapillary venules with mononuclear cell infiltrates in all layers of the involved blood vessels, fibrinoid necrosis in active lesions, and thrombosis associated with intimal proliferation. Early and more aggressive treatment for RA has improved disease outcome and thus also contributed to decreased prevalence of RV. A retrospective review of RV in a single large center characterized RV patients as having more severe, erosive RA of longer duration that was inactive [14]. Other risk factors included presence of subcutaneous nodules, high-titer RF, active smoking at the time of diagnosis, coexisting cardiovascular disease, and the use of biologic modifiers. The clinical features of RV are variable and include palpable purpura, cutaneous ulcerations, distal arteritis ranging from fingernail-fold infarcts and splinter hemorrhages to digital gangrene, and vasculitic neuropathies. Arteritis of other major organs including the gastrointestinal tract, kidneys, heart, and lungs is clinically similar to polyarteritis nodosa. Patients with RV often present with constitutional symptoms of malaise, weight loss, fevers, and have elevated inflammatory markers, anemia, leukocytosis, hypocomplementia, and elevated RF and/or ACPA. Mortality remains high for RV, and necrotizing forms of RV are associated with a poor prognosis and are treated aggressively with high-dose corticosteroids and cytotoxic agents such as cyclophosphamide similar to treatment for polyarteritis nodosa (see Chapters 67 and 68).

**Neurologic Complications of Rheumatoid Arthritis**

All components of the nervous system can be affected by RA. The brain and meninges, spinal cord, peripheral nerves, and muscles may be involved with granulomatous inflammation in the form of rheumatoid nodules or vasculitis; the spinal cord and cranial and peripheral nerves may also be compressed by skeletal and soft tissue structures, and the nervous system may be affected by hyperviscosity syndrome and medications.

Spinal cord compression is one of the most common neurologic complications among patients with RA, as discussed in the previous section. Manifestations that require immediate intervention include the sensation of anterior instability of the head during neck flexion, drop attacks, loss of urinary bladder and anal sphincter control, dysphagia,
vertigo, hemiplegia, dysarthria, nystagmus, changes in level of consciousness, and peripheral paresthesias without evidence of a peripheral cause. Although RA patients may have radiographic evidence of cervical subluxation without symptoms, once signs of cord compression become apparent, myelopathy may progress rapidly. For patients with manifestations of spinal cord and brain stem compression, surgical stabilization is indicated. For the nonsurgical candidate, a firm collar can be used in an effort to immobilize the neck and prevent further subluxation.
SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune disease whose pathogenesis is likely multifactorial, involving genetic predisposition, hormonal factors, environmental triggers, and immune dysregulation. The resultant excessive autoantibody production and immune complex deposition in multiple organ systems manifest in tremendous clinical variations and range from arthralgias, rash, and fatigue to life-threatening renal, central nervous system (CNS), cardiac, pulmonary, or hematologic manifestations. Diagnosis of SLE is based on the clinical criteria set forth by the American College of Rheumatology [15]. Mortality of SLE patients admitted to the ICU is much higher than the general ICU population and is associated with high APACHE scores, older age, multisystem dysfunction, and cytopenias [16]. Among ICU patients with established SLE, it is essential to differentiate problems caused directly by SLE activity from those with secondary causes such as infections, drug-induced lupus (DIL), NSAID-induced renal dysfunction, aseptic meningitis, and corticosteroid-induced psychosis. Diseases associated with SLE include avascular necrosis, hypertensive encephalopathy, pseudotumor cerebri, amyloidosis, myasthenia gravis, and thrombotic thrombocytopenic purpura (TTP). Among ICU patients without a prior history of autoimmune disease, SLE should be considered in the differential diagnosis of patients presenting with acute renal failure, seizures, myocarditis, acute pulmonary deterioration, hemolytic anemia, or thrombocytopenia.

Renal Disease

Renal involvement is the major cause of disease-related mortality in SLE patients. The frequency of renal involvement ranges from 38% to nearly 80% depending on definition, but clinical lupus nephritis (LN) occurs in approximately 50% of the patients. Advances in diagnostic and therapeutic modalities have dramatically improved the survival of lupus patients with renal disease, but 10% to 20% of patients will develop end-stage renal disease. LN constitutes approximately 3% of all end-stage renal failure among patients on dialysis or requiring renal transplantation. Weighted mean of number of renal transplants per study detailed patient survival at 1, 3, 5 years to be 93.3%, 70.1% and 53.3%, respectively, whereas graft survival at 1, 3, 5 years was 85.1%, 60.3%, and 43.9%, respectively [17]. Recurrence of LN has been reported to be around 2.4% in surveillance studies, and risk factors include African American race, young age, and female gender [18].
Classification of LN is based on histopathologic, immunofluorescent, and electron microscopic changes according to the 2003 revised classification by the International Society of Nephrology and the Renal Pathology Society (ISN/RPS) [19]. The classification includes the following: Class I: minimal mesangial LN; Class II: mesangial proliferative LN; Class III: focal proliferative LN; Class IV: diffuse proliferative LN with two subclasses, segmental and global; Class V: membranous LN; and Class VI: advanced sclerosing LN. Classes III and IV are divided into active or chronic, whereas Class IV is further subdivided into segmental or global. Renal lesions are commonly pleomorphic, vary from one glomerulus to another, and temporally transition from one class to another over time. The tubulointerstitium and vasculature are often involved. Semiquantitative scoring to define activity and chronicity may provide information on prognosis and guidelines for therapeutic options. In particular, the presence of proliferative lesions and chronic lesions is associated with greater mortality.

Other SLE renal manifestations aside from immune-mediated glomerular disease include tubulointerstitial disease (usually occurring concurrently with LN but may exist in isolation), vascular disease (vasculitis, thrombotic microangiopathy related to lupus anticoagulant [LA] or antiphospholipid antibodies [aPL], atherosclerotic disease, or thromboembolism). Diagnosis of these processes may require histopathology because treatment may differ from immune complex–mediated LN.

The clinical manifestations of renal involvement vary from rapidly progressive renal failure with attendant fluid overload, to congestive heart failure or accelerated hypertension, and are common events precipitating an ICU admission. A sudden deterioration in an SLE patient’s renal function warrants careful consideration of other causes of acute renal insufficiency (see Chapter 200) before attributing the deterioration to active SLE. In particular, hypovolemia, drug-induced interstitial nephritis or renal insufficiency, renal vein thrombosis, and contrast-induced acute tubular necrosis must be excluded. Physical examination may reveal evidence of SLE activity in other organ systems. Laboratory studies should include routine tests to assess renal status and fluid balance, and immunologic studies, including double-stranded DNA (dsDNA) antibody, total hemolytic complement, third (C3) and fourth (C4) complement components and ESR. Active serologies suggest SLE flare, but normal values do not exclude active disease. Renal biopsy is often necessary for diagnosis and informs therapeutic decisions.
Management of LN depends on the patient’s renal histopathologic and functional parameters. Thus, a patient with Class I or II LN with normal creatinine clearance requires no specific therapy, whereas a patient with increasing azotemia, active urinary sediment, and impaired clearance requires aggressive therapy. For patients with severe glomerulonephritis (ISN/RPS Class III or IV), induction therapy includes the combination of high-dose corticosteroids with IVCY or oral MMF for 6 months followed by maintenance therapy, which stabilizes renal function and improves survival. The equivalency of MMF up to 3 g per day compared to monthly IVCY as induction therapy for Class III, IV, or V LN has been established by several trials including a large international trial conducted by the ALMS group (Aspreva Lupus Management Study), which confirmed this equivalence of both induction regimens at the end of 24 weeks with a response rate of 56% in each group [20]. However, only 8% from either treatment group reached complete remission. In addition, patients of Hispanic and African descent had a much better response to MMF than IVCY (60% vs. 38%), whereas whites and Asian patients responded equally to either regimen. The risk for gonadal failure was less with MMF, but other toxicities such as infections were similar. Another option for IVCY induction is the low-dose regimen from the Euro-Lupus Nephritis Trial, which demonstrated equal efficacy and less gonadal toxicity between low-dose IVCY (500 mg every 2 weeks for six doses) and high-dose IVCY (500 to 750 mg per m² with maximum of 1,500 mg, monthly for 6 months, followed by every 3-month infusion until 1 year) [21]. Both groups then received azathioprine (AZA) at 2 mg/kg/d for maintenance. The long-term outcomes measured by death, end-stage renal disease, and doubling of serum creatinine were similar in both groups after 10 years [22]. This regimen also had less gonadal toxicities.

Although not a pressing decision in SLE patient with acute nephritis, current recommendations for maintenance therapy once induction is completed include either AZA or MMF. A large randomized, double-blind, double-dummy trial for 36 months demonstrated superiority of MMF to AZA in preventing renal relapse and maintaining response [23].

In an acutely ill ICU patient with LN and/or other organ system involvement, IVCY along with pulse IV methylprednisolone at 1,000 mg daily for 3 days may be the regimen of choice because many of the studies have not stratified for disease severity. Patients may not be able to take oral MMF. The protocol for administration of monthly IVCY therapy is outlined in Table 66.7. Dose adjustments for renal insufficiency are outlined and subsequent monthly dosing is based on nadir WBC counts. Alternative regimen would be the low-dose Euro-Lupus regimen [21].

Membranous GN (Class V), which constitutes 20% of LN, is less aggressive than Class IV GN. Although renal survival rate is at 80% at 10 years, it is still associated with significant comorbidities of
hyperlipidemia, and cardiovascular and thromboembolic diseases. Angiotensin-converting enzyme (ACE) inhibitors have been used successfully to reduce proteinuria. Treatment with corticosteroids, AZA, and cyclosporine has been studied in small series. More recently, the pooled subset of Class V patients from two prospective randomized studies on treatment of GN demonstrated equivalent efficacy and safety profile of MMF and IVCY [24]. Adjunctive renoprotective therapies that include aspirin, statins, ACE inhibitors, or angiotensin receptor blockers should also be instituted.

Advances of biologic therapies for RA and psoriatic arthritis have also stimulated investigations for SLE. Initial open label studies and case reports suggest promising results with the use of RTX, an anti-CD20 B-cell-depleting monoclonal antibody, for reducing SLE activity. Surprisingly, a randomized trial comparing RTX to placebo with a background of MMF for active proliferative LN revealed no additional benefit, and another study on active nonrenal SLE was also negative [25]. Belimumab, a human immunoglobulin G (IgG)1 λ monoclonal antibody against activity of soluble B-lymphocyte stimulator, whose levels are associated with lupus disease activity, has been approved for use in SLE. Randomized trials have demonstrated decreased lupus activity when compared to placebo among patients receiving standard care. In a post hoc pooled analysis of the trials with belimumab, there appeared to be additional renal benefit for patients receiving MMF and belimumab compared to those receiving placebo [26].

Neuropsychiatric Disease

Neuropsychiatric systemic lupus erythematosus (NPSLE), which encompasses involvement of the central, peripheral, and autonomic nervous systems along with psychiatric syndromes, occurs in 25% to 80% of SLE patients depending on the criteria applied or methods used for diagnosis. Although NPSLE was considered a poor prognostic indicator in the older literature, it does not seem to have significant impact on survival rates. Active CNS disease contributed primarily or secondarily to death in only a small percentage of patients.

Neuropsychiatric manifestations of SLE can be classified into central versus peripheral nervous system involvement. Due to the limitations of the ACR classification criteria of CNS involvement, an ad hoc neuropsychiatric lupus nomenclature committee of the American College of Rheumatology defined 19 manifestations that included 12 in the CNS and 7 in the peripheral nervous system [27] (Table 66.2). The wide range
of prevalence for the more diffuse CNS syndromes (cognitive dysfunction, anxiety, acute confusional states, and psychoses) and headache is due to the variable definition, criteria, or diagnostic parameters used among reported studies. This proposed nomenclature attempts to define the spectrum of NPSLE, but is not a substitute for clinical diagnosis. An individual SLE patient may have multiple neuropsychiatric manifestations, and these can develop prior to the formal diagnosis of SLE or during an inactive disease state. Frank psychosis is relatively rare, estimated at 5%. Often, it is difficult to separate active lupus psychosis from other causes such as functional disorders, uremia, illicit drug use, metabolic disturbances, medications, or infections.

Peripheral neuropathy
  Polyneuropathy (3%–28%)
  Mononeuropathy, single or multiplex
  Plexopathy (<1%)
Cranial neuropathies (4%–49%)
  Acute inflammatory demyelinating polyradiculoneuropathy (Guillain–Barré syndrome) <1%
Autonomic neuropathy (<1%)
Myasthenia gravis (<1%)

Focal CNS disease, including seizures that occur in 15% to 35% of SLE patients, can antedate the diagnosis of SLE or develop any time during the disease course. Grand mal seizures are the most common, but essentially all types have been reported. Secondary causes of seizures must be sought because several prospective studies of SLE patients with neurologic events reported that a majority of seizures were due to associated infections, uremia, hypertension, and metabolic abnormalities.

Cerebrovascular accidents (5% to 18%) include infarctions secondary to intracranial hemorrhage or arteritis, thrombosis from LA or aPL-associated hypercoagulable states (see “Antiphospholipid Syndrome” section), or embolism from Libman–Sacks endocarditis. Movement disorders including chorea, ataxia, and hemiballismus are rare (<1%) [28]. Transverse myelitis is an unusual but devastating complication of SLE characterized by acute or subacute paraplegia or quadriplegia associated with sensory level deficit and loss of sphincter control. Cerebrospinal fluid (CSF) analysis reveals pleocytosis, low CSF glucose, and high CSF protein. T2-weighted MRI usually demonstrates increased signal intensity and cord edema. Meningitis, usually infectious, may develop in SLE patients. However, aseptic meningitis can be idiopathic or secondary to administration of ibuprofen or AZA.

Peripheral nervous system syndromes include cranial neuropathies (4% to 49%) such as facial palsies and ocular muscle dysfunction. Pure sensory or motor abnormalities based on electromyography/nerve conduction studies occur in up to 47%, but plexopathy, Guillain–Barré syndrome, and autonomic neuropathy are rare.
The differentiation of NPSLE from other CNS disorders is difficult and remains a process of elimination. CSF pleocytosis and low glucose require exclusion of infections. Electroencephalography generally reveals diffuse brain wave slowing, but focal activity suggests seizures. The presence of serum antiribosomal P (phosphorylated protein) antibodies are not useful for confirming lupus psychosis, but rather just the diagnosis of SLE. The gold standard for imaging the CNS in SLE is conventional MRI with gadolinium. CT scans are less sensitive and should be reserved for patients in whom MRI is contraindicated or for emergent situations to document bleed, infarct, cerebral edema, or a mass lesion. Focal lesions of the subcortical white matter are the most common MRI findings and correlate with ischemic changes. Changes in the gray matter that brighten on T2-weighted imaging suggest more acute events and may improve with therapy. However, it is often difficult to distinguish acute from chronic MRI lesions, and subcortical lesions are found in up to 50% of patients without any neuropsychiatric symptoms. Angiography is invasive and rarely results in an accurate diagnosis of active CNS lupus. Because the sensitivity of MRI for patients with cognitive or affective symptoms is low, additional imaging techniques have been evaluated. Single-photon emission computerized tomography, which measures functional cerebral blood flow, has low specificity. Magnetic angiography, magnetic resonance spectroscopy, magnetic transfer imaging, and perfusion- and diffusion-weighted imaging are still viewed only as research tools, and their roles in assessment of NPSLE remain to be determined.

Management of SLE patients with neuropsychiatric manifestations should focus on specific neurologic symptoms. Non-SLE causes of CNS disease, including infections, uremia, hypertension, metabolic disturbances, hypoxia, or drug toxicities, must be identified and treated appropriately. If lupus cerebritis is suspected, a brief doubling of the steroid dose for 3 days may exclude the possibility of a diffuse CNS syndrome. If there is no improvement or no evidence of active lupus, the steroid dose should be tapered. Seizures are treated with appropriate anticonvulsant medications. Status epilepticus is treated with anticonvulsants and high-dose steroids. Psychotic patients should receive antipsychotic agents. High-dose steroids have been recommended for neuropsychiatric lupus; dosages range from 1.0 to 1.5 mg/kg/d, or its equivalent. In severe cases, pulse IV methylprednisolone in a dose of 1,000 mg per day for 3 days is preferred. As for immunosuppressive agents, few prospective studies of treatment of NPSLE have been performed. A recent Cochrane database review of therapy for neuropsychiatric lupus found only one controlled clinical trial that suggested better outcomes with monthly IV CY than steroids alone [29]. Limited case reports of RTX therapy in NPSLE suggest efficacy, but no randomized studies are available. Transverse myelitis has been treated
successfully with pulse methylprednisolone, IVCY, and plasmapheresis.

Pulmonary Disease

The pleuropulmonary manifestations of SLE are common and can involve the pleura, parenchyma, vasculature, diaphragm, or airways (see Table 66.1). Acute pulmonary symptoms can be the initial presentation of SLE that results in an ICU admission, whereas the prevalence of long-term lung damage (11.6% by 10 years of disease duration) can contribute to SLE morbidity and mortality [30].

Pleuritis with or without effusions has been reported in 30% to 50% of patients with SLE, depending on the method of study (i.e., clinical history, radiograph findings, or autopsy findings) [31]. Pleural effusions are usually small and bilateral, but massive collections can occur. Thoracentesis is indicated when the etiology of the fluid is uncertain or if respiratory compromise is present. Pleural fluid is characteristically exudative with high protein, pH is variable but can be low, and glucose slightly decreased in contrast to the uniformly low glucose and pH seen in rheumatoid pleural effusions. WBC counts are elevated and consist predominantly of PMNs or lymphocytes. Mild pleuritis usually responds to NSAIDs or low-dose corticosteroids (0.5 mg/kg/d prednisone or its equivalent). The latter is used only after infection has been excluded.

Acute lupus pneumonitis (ALP), although uncommon (0% to 14%), may be the initial presentation of SLE and can be life threatening [31]. It cannot be differentiated from other forms of bronchopneumonia, and thus infectious etiologies should be excluded by appropriate studies. Clinically, patients present with fever, severe dyspnea, tachypnea, and hypoxemia. Chest radiographs reveal patchy alveolar infiltrates, usually basilar in location. Mortality is as high as 50%. Transbronchial brushings with biopsies and BAL may help exclude infections and malignancies. High frequency of anti-SSA/SSB antibodies has been associated with ALP. Given the poor prognosis, therapy requires high-dose corticosteroids (1 to 2 mg/kg/d) or pulse IV methylprednisolone (1,000 mg IV daily for 3 days) along with broad-spectrum antibiotics until final cultures return. Case reports suggest the use of IVCY, RTX, or IV immunoglobulins in patients who respond poorly to steroids.

Pulmonary hemorrhage is a rare but potentially fatal complication. Patients characteristically present with acute dyspnea, tachycardia, severe hypoxemia, rales, sudden drop in hematocrit, and hemoptysis. Rarely, diagnosis is delayed because of the absence of hemoptysis. BAL provides the most reliable confirmation with the presence of bloody fluid,
hemosiderin-laden macrophages, purulent sputum, and absence of pathogenic organisms on culture and Gram stain. Pathologic findings include intra-alveolar hemorrhage sometimes associated with interstitial pneumonitis or capillaritis, but pathology may only be bland hemorrhage. Immunopathologic studies may reveal granular deposition of IgG in alveolar septal walls and pulmonary vessels, thus suggesting a possible immune complex-mediated process. Therapy is generally aggressive with IV methylprednisolone at 1,000 mg daily for 3 days followed by tapering high-dose oral (1 mg/kg/d) corticosteroids. The addition of IVCY should be considered for patients who are critically ill or fail pulse corticosteroids. Plasmapheresis has been added in case reports, but whether it offers any additional benefit is unclear. Mortality remains high at 80% despite such treatment. (See Chapter 175 for an in-depth discussion of intrapulmonary hemorrhage and pulmonary-renal syndromes.)

The prevalence of ILD is less than 3% according to several studies and may occur before or after ALP. Patients usually present with dyspnea on exertion, productive cough, pleuritis, and rales. Pulmonary function tests reveal a restrictive pattern and marked reduction in diffusing capacity. High-resolution thin-section CT may differentiate earlier-stage alveolitis from end-stage fibrosis. The presence of dense alveolar opacities or “ground glass” appearance suggests active inflammation and may guide therapy. The pathology of SLE ILD is similar to those seen in RA and includes NSIP, LIP, and OP. Treatment for ILD is challenging, and there are no prospective randomized trials for specific SLE ILD, but management is similar to rheumatoid lung disease or those with idiopathic interstitial pneumonia. Therapy for symptomatic disease begins with high-dose corticosteroids and again, IVCY, AZA, or MMF has been used in clinically progressive ILD or for steroid sparing.

Pulmonary arterial hypertension (PAH) in SLE is the second most common connective tissue disease–related PAH after SSc, but is a rare complication of SLE, estimated at 4% when other causes of pulmonary hypertension are excluded. Patients usually present with severe dyspnea on exertion, palpitations, and fatigue. Pathologically, changes of intimal thickening and fibrosis, medial hypertrophy, altered elastic laminae, and periadventitial fibrosis have been similar to changes seen in idiopathic pulmonary hypertension, but also findings of inflammatory cell infiltrates and immune deposits have been reported. Other associated factors for PAH include the presence of Raynaud’s phenomenon (RP) and aPLs. Often, symptoms develop late in the clinical course, and thus assessment with Doppler echocardiography is useful to monitor for progressive disease requiring therapy.

Therapy for primary pulmonary hypertension is evolving rapidly with the use of prostacyclin agonists, endothelin receptor antagonists,
phosphodiesterase inhibitors, soluble guanylate cyclase stimulator, or combination therapies. Most of these drug studies for pulmonary hypertension have included patients with connective disease–associated PAH (see the section “Systemic Sclerosis” and Chapter 174 on pulmonary hypertension). Given the pathologic findings of inflammation and immune deposits, immunosuppression with steroids, cyclophosphamide, and even RTX have been suggested for early-stage PAH along with conventional therapy, but these are based on limited retrospective or case report studies [33]. Pulmonary embolism and peripheral vaso-occlusive disease are well-known risks for SLE patients. One prospective study documented the risk of deep vein thrombosis at approximately 12%, with a 9% risk for pulmonary embolism. The risk of thromboembolic events is increased in patients with LA and aPLs (see “Antiphospholipid Syndrome” section).

Other rare pulmonary syndromes occur in SLE. Dyspnea from shrinking lung syndrome can be either acute or chronic and has a prevalence of 0.5% to 0.9% [30,31]. Postulated mechanisms include myopathy of respiratory skeletal muscles or diaphragm, phrenic neuropathy, or pleural inflammation. Pulmonary function tests reveal reduced total lung volumes with a restrictive pattern, whereas imaging reveals low lung volumes, atelectasis, but no evidence of ILD. Treatment is usually with corticosteroids, but immunosuppressive agents have been used for refractory cases. Acute reversible hypoxemia, possibly secondary to pulmonary leukocyte aggregation, has been described among acutely ill SLE patients. Patients present with severe hypoxemia, hypocapnia, and increased alveolar-arterial PO\textsubscript{2} gradient without obvious parenchymal lung disease. Treatment with high-dose glucocorticoids improves oxygenation. Cricoarytenoid or laryngeal involvement causing upper airway obstruction varies from 0.3% to 30% [31]. Bronchiectasis is common, but usually clinically asymptomatic.

Cardiac Disease

Cardiovascular involvement of SLE ranges from 29% to 66%. This tremendous range reflects whether data are based on clinical parameters or pathologic findings at autopsy. Often, the latter studies document significant findings in the heart without clinical correlation. However, a multisite international SLE cohort study confirmed that circulatory disease (including cardiac, arterial, and cerebral vascular disease) is the major cause of mortality [34].

Pericardial disease is by far the most common cardiac manifestation of
SLE but less common than lupus pleuritis, and subclinical pericarditis is often documented only at autopsy. Pericarditis usually presents in association with other organ system activity, rather than as an initial manifestation of SLE. Symptoms, physical exam findings, and diagnostic cardiac testing are similar to idiopathic pericarditis, but some SLE patients may have relatively normal findings.

Life-threatening complications of pericarditis include cardiac tamponade and constriction. Both entities are rare and thus pericardiocentesis fluid data are limited. Typically, pericardial fluid is exudative with high protein and normal-to-low glucose, compared with serum. The total WBC counts from various reports have ranged from 544 to 199,600 cells per μL, with predominantly PMNs [35]. Therefore, suppurative pericarditis becomes a significant and important consideration for SLE patients with pericarditis. Other reported pericardial fluid features of low or absent complement levels, lupus erythematosus cells on Wright stains, and ANA titers are not clinically useful. Constrictive pericarditis may develop after successful treatment of pericarditis with or without corticosteroids.

Once other causes of pericarditis, including uremia, drugs, or viral infections, have been eliminated, hemodynamically stable but symptomatic pericarditis can be successfully treated with NSAIDs or, occasionally, moderate-dose oral corticosteroids (0.5 mg/kg/d). If fever is present and the etiology of the pericardial effusion is not clear, a diagnostic pericardiocentesis may be necessary to rule out bacterial or opportunistic infections. Hemodynamically compromising effusions require pericardiocentesis and high-dose IV corticosteroids (e.g., equivalent of 1 mg/kg/d), and rarely, pericardial window or pericardiectiony may be required.

Another common cardiac manifestation of SLE is valvular heart disease involving the mitral, aortic, or tricuspid valves, often asymptomatic and discovered on echocardiography. Thickened leaflets are common echocardiographic findings but nonbacterial, verrucous lesions (Libman–Sacks endocarditis) may result in embolic events, secondary infectious endocarditis, or valvular insufficiency or stenosis. At autopsy, 15% to 60% of SLE patients have lesions composed of immune complexes, fibrin, platelets, and fibrotic changes on the ventricular surface of the mitral valve (and, less commonly, aortic valve), ventricular endocardium, chordae tendineae, and papillary muscle. Clinically, the presence of these lesions does not correlate with murmurs. Prevalence varies from 11% by transthoracic echocardiogram to 43% by transesophageal approach [36]. In a large meta-analysis to assess the association of aPLs and valvular disease/Libman–Sacks endocarditis in SLE patients, there was a threefold higher risk for any heart valve lesion in SLE patients with aPL than in those without aPL and a 5.3-fold risk for those patients who have
both LA and IgG aPL [37]. In patients with aPL and valvular disease, antiplatelet medications are recommended, whereas full anticoagulation is recommended for those with documented embolic events. If significant valvular dysfunction occurs, valve repair or replacement may be required, but complications include rapid calcification of the repaired valve or bioprosthesis.

Myocardial involvement in SLE is the least frequent manifestation of cardiac disease and should be categorized as primary or secondary. Primary myocarditis is rare, clinically occurring in 10% of SLE patients [38]. Myocarditis has been defined as unexplained tachycardia, congestive heart failure, ventricular arrhythmias, conduction defects, ST- or T-wave changes, or cardiomegaly without evidence of valvular or pericardial disease. Congestive heart failure from myocarditis is rare and is estimated to occur among 4% of cases. Echocardiogram may reveal global hypokinesis, whereas cardiac MRI with gadolinium has delayed contrast enhancement. Secondary myocardial dysfunction of SLE includes systemic hypertension, valvular disease, pulmonary disease, coronary artery ischemia (see following discussion), drug toxicity, and amyloidosis. These secondary causes are often more important than true lupus myocarditis. Management of patients with evidence of carditis rests on distinguishing primary from secondary disorders. For the rare patient who has myocarditis from SLE, high-dose corticosteroids are indicated. Data regarding the use of immunosuppressive agents are scarce.

Primary coronary artery involvement in SLE includes embolic events, thromboses, or a true vasculitis of the vessels as opposed to secondary changes of premature atherosclerosis. Coronary arteritis is rare and difficult to distinguish from atherosclerosis on arteriographic studies unless repetitive studies are performed. This can occur in the absence of extracardiac SLE activity. Thrombosis associated with aPL may contribute to myocardial ischemia.

Accelerated atherosclerosis, however, is the most serious cause of morbidity and mortality among SLE patients and especially for the age group between 35 and 44 years. A recent systemic review on the epidemiology of atherosclerotic cardiovascular disease (including coronary artery disease, peripheral vascular disease, congestive heart failure, and cerebral vascular disease) in SLE patients revealed two to threefold risk compared to the general population and even higher risk for young SLE patients (age <45 years) [39]. Traditional risk factors including smoking, diabetes, hypertension, hyperlipidemia, obesity, family history, and sedentary lifestyle are common among the SLE population, but the additional effects of medications such as glucocorticoids, chronic inflammation, and hypercoagulability may also contribute to the significantly higher risk for cardiovascular disease. The management of SLE patients with acute myocardial ischemia initially is
similar to any patient with atherosclerotic coronary artery disease. However, the etiology of the ischemia must be determined because management of coronary arteritis differs from management of atherosclerotic disease. Evidence of extracardiac SLE activity may be helpful. Laboratory tests, including ANA, anti-dsDNA, complement levels, complete blood count with differential, and platelet counts may provide some indicators of SLE activity. LA and aPLs should be checked. Coronary arteriogram may be helpful in separating thrombosis and vasculitis from atherosclerosis. However, arteriographic distinction of the latter two may be difficult. If arteriography reveals thrombosis without evident atherosclerosis and the presence of aPLs is documented, therapy should consist of anticoagulation and antiplatelet medications.

Conduction abnormalities and arrhythmias due to SLE are usually clinically insignificant. The incidence of atrioventricular nodal block is estimated to be 5%. Sinus tachycardia without underlying pathology (fever, dehydration, congestive heart failure, thyroid disease, drug abuse) may be a subtle manifestation of lupus activity. If acute conduction disease is suspected clinically to be secondary to myocarditis or arteritis, a short trial of corticosteroids could be initiated in the hemodynamically compromised patient.

Hematologic Disease

Hematologic abnormalities constitute one of the major criteria for SLE. These include hemolytic anemia, thrombocytopenia, leukopenia, and lymphopenia. Anemia is present in the majority of SLE patients, with anemia of chronic disease being the most common etiology. Other causes of anemia include iron deficiency (blood loss from menses or gastrointestinal tract, or poor iron absorption because of increased hepcidin levels), autoimmune hemolytic anemia (AIHA), drug induced (cyclophosphamide or AZA), pure red cell aplasia, and chronic renal insufficiency. Rarely, other syndromes including TTP and macrophage activation syndrome have been reported in SLE patients who have more than two cell lines affected.

Only 8% to 28% of lupus patients develop AIHA sometime during the course of their disease. Although 18% to 65% of SLE patients have a positive direct Coombs assay, significant hemolytic anemia develops in only 10% [40]. The presence of warm IgG autoantibodies and complement on the red cell surface is characteristic of SLE AIHA. Clinically, AIHA is accompanied by an elevated reticulocyte count and indirect bilirubin and decreased haptoglobin levels. Severe hemolytic
anemia, defined as hemoglobin <8 g per dL, is often associated with concomitant seizures, nephritis, serositis, and other cytopenias. In addition, 74% of patients with AIHA will have aPLs. Over 75% to 96% of patients with AIHA respond rapidly to high-dose corticosteroids (60 to 100 mg per day prednisone orally or with IV methylprednisolone at 1.5 mg/kg/d) [40]. Prednisone is tapered slowly after 4 weeks, based on laboratory results. If active hemolysis persists after 4 weeks, other therapeutic modalities include danazol, immunosuppressive agents, and splenectomy; however, splenectomy induces permanent remission in fewer than 50% of patients. Combination of high-dose steroids and danazol, 800 to 1,200 mg per day, is an alternative treatment for severe AIHA, with subsequent gradual steroid tapering. One retrospective study of SLE patients treated for AIHA suggests that danazol was the most effective long-term treatment [41]. The short-term efficacy of IVIG is not sustained. Uncontrolled trials or case reports with AZA, RTX, MMF, or cyclophosphamide have shown therapeutic response.

Thrombotic microangiopathy (TMA) pathologically classifies a group of disease that include thrombotic thrombocytopenic purpura (TTP). The latter is characterized by thrombocytopenia, hemolytic anemia and sometimes with renal or neurologic systems and has been described in SLE. Markedly reduced ADAMTS-13 protease (A Disintegrin And Metalloprotease with a ThromboSpondin type 1 motif, member 13) results in persistence of ultralarge von Willebrand factor multimers on the endothelial surface, which is felt to cause TMA. Among patients with SLE, this deficiency is acquired because of the presence of an inhibitor against the protease. Initial presumptive diagnosis is based on clinical presentation of microangiopathic features, thrombocytopenia, fever, nervous system involvement with mental status changes, and renal insufficiency because ADAMTS-13 results may be delayed. Immediate treatment, similar to idiopathic TTP, with high-dose steroids and plasma exchange is life saving.

Leukopenia, defined as a total WBC count of less than 4,000 per μL, occurs in 50% to 60% of SLE patients, but rarely associated with infectious complications unless CD4 counts are below 200. For febrile, severely neutropenic patient, granulocyte-stimulating factor has been used. Lymphopenia, defined as counts lower than 1,500 per μL, is seen among 84% of SLE patients during active disease.

Thrombocytopenia, or platelet counts lower than 100,000 per μL, is observed among 20% to 40% of SLE patients and is severe (less than 50,000 per μL) among 10% of patients. Idiopathic thrombocytopenic purpura (ITP) may be the initial presentation of SLE. When evaluating any patient with thrombocytopenia, underlying causes including drug toxicities, ineffective thrombopoiesis, congestive splenomegaly, dilutional effects, abnormal platelet destruction by disseminated intravascular
coagulation (DIC), antiphospholipid syndrome (APS), TTP, hemolytic uremic syndrome (HUS), vasculitis, drug-induced infection, or other hematologic disorders should be excluded. The pathologic mechanism is usually antiplatelet antibodies, with resultant splenic sequestration and decreased platelet life span, although there is association with elevated aPL as well. A bone marrow biopsy is helpful for distinguishing various forms of thrombocytopenia. SLE-associated ITP is characterized by an increased number of megakaryocytes.

Once TTP, HUS, DIC, and drug toxicities are excluded, therapy of severe SLE-associated ITP (less than 30,000 per μL) is similar to that of idiopathic autoimmune thrombocytopenia. Corticosteroid therapy at 1 mg/kg/d is the recommended initial therapy. Subsequent tapering is guided by platelet counts. Administration of IVIG may result in a rapid increase in platelet counts when patients are having acute bleeding or need invasive procedures, but the response is usually not sustained. Recommended dose is 1.0 g per day for 2 to 3 days based on platelet counts. Splenectomy is an option for SLE patients who fail medical therapy, with improved thrombocytopenia in 84% of patients in a median follow-up of 6.6 years after splenectomy [42]. Some of these patients had partial response and required additional medical therapy. For refractory disease, danazol, 800 to 1,200 mg per day alone or in conjunction with corticosteroids, has been effective in several studies. In a meta-analysis, rituximab is effective for idiopathic thrombocytopenia in conjunction with or after failure to respond to glucocorticoids [43]. Given this report and case reports of success in the literature for SLE-associated ITP, it is one of the second-line agents to consider. Other second-line immunosuppressive agents include cyclophosphamide, MMF, and AZA.

LA interferes with the activation of prothrombin activator complex (factors Xa and V, Ca²⁺, and phospholipid) of the intrinsic and extrinsic pathways. The laboratory findings are markedly prolonged partial thromboplastin time and normal or mildly prolonged prothrombin time that cannot be corrected by mixing with normal plasma. In addition, patients may also have false-positive reactions in the test for syphilis (VDRL). (Please see the section “Antiphospholipid Syndrome” for clinical details.) Although many SLE patients have both LA and aPLs, subsets of patients have only one or the other laboratory abnormality and still develop clinical manifestations of APS.

Gastrointestinal Disease

Gastrointestinal involvement of SLE is not frequently considered because many gastrointestinal symptoms can be attributed to complications of drug therapy, particularly salicylates, NSAIDs, corticosteroids, hydroxychloroquine, and AZA. The prevalence of SLE-related
gastrointestinal disease varies from of 8% to 22% and includes serositis, mesenteric vasculitis or thrombosis, pancreatitis, cholecystitis, inflammatory bowel disease, protein-losing enteropathy, intestinal pseudo-obstruction, and pneumatosis intestinalis [44].

The most serious but rare (<1%) gastrointestinal complication of SLE is mesenteric vasculitis or thrombosis with subsequent large or small intestinal ischemia. The severity and extent of involvement vary and symptoms may be chronic or acute in presentation. Intestinal involvement ranges from segmental edema or ulcerations to perforations. Evaluation should include plain films, paracentesis (to rule out perforation or bacterial peritonitis), CT scans, or angiography. Although features of dilated bowel, bowel wall edema or enhancement, or edema of the mesentery or its vessels are nonspecific, multiple vessel involvement, often in the areas of ileum and jejunum, is found in SLE mesenteric vasculitis. However, angiographic results may be normal because of small vessel disease. Direct visualization with endoscopy or colonoscopy may also provide useful information.

Lupus peritonitis is less devastating but often quite dramatic in presentation. Peritoneal fluid may be present, and is usually transudative and sterile with a low cell count. Other causes of ascites must be ruled out, including constrictive pericarditis, nephrotic syndrome, and spontaneous bacterial peritonitis. Pancreatitis attributed to active SLE is rare and more often related to the usual causes of pancreatitis in non-SLE patients (e.g., drugs, hepatobiliary infection, alcohol, etc.) [45]. Protein-losing enteropathy and intestinal pseudo-obstruction were the most common gastrointestinal manifestations among hospitalized SLE patients [44].

Management of the SLE patient with abdominal pain does not differ significantly from that for non-SLE patients. For patients with mild-to-moderate pain with a chronic course, medications and intercurrent disease should be considered first as the cause of pain and surgical consultation obtained. When no etiology is found, peritonitis should be considered and treated with a moderate increase in steroids. For patients who present acutely, supportive care should be started and appropriate laboratory and imaging studies performed. Paracentesis should be done to exclude perforated viscus or infection. A therapeutic trial of high-dose steroids can then be instituted if mesenteric vasculitis is suspected. Rapid (12 to 48 hours) response usually is consistent with vasculitis or peritonitis, although complete response is often delayed; if a patient deteriorates clinically, exploratory laparotomy is necessary. When studies
suggest mesenteric vasculitis, IVCY may be necessary along with the corticosteroids.

**Drug-Induced Lupus**

The syndrome of DIL should be considered for ICU patients when systemic symptoms of fever, arthralgias, arthritis, pleuroperticarditis, and, less commonly, rash are present. Because many ICU patients receive medications that potentially induce SLE (see Table 66.3), the diagnosis must be excluded. Although some medications, particularly procainamide, hydralazine, and TNFα inhibitors, produce positive ANA tests, this does not necessarily imply that DIL is present. Symptoms typically develop several months after the institution of the offending medication. Although CNS and renal manifestations are rare, case reports of more atypical DIL have been reported. Males and females are equally susceptible. DIL is more common among older patients, except for minocycline-related DIL (younger and more females). Laboratory values reveal an elevated ESR, mild leukopenia or thrombocytopenia, and positive ANA; antihistone antibodies are present in 90% of patients; and specific antibodies to dsDNA and Smith (Sm) antigen are uncommon. However, TNFα inhibitors such as etanercept or infliximab have been associated with anti-dsDNA, anti-Ro, anti-Sm, and antineutrophil cytoplasmic antibodies. Complement levels are normal with DIL.

\*Rare: usually case reports.

Subacute cutaneous lupus (SCLE), with characteristic annular or psoriasiform lesions that are photosensitive, is associated with drugs that differ in frequency than those listed in Table 66.3. A review of all patients with SCLE reported that about 38% had exposure to the following drugs that were felt to be causative: terbinafine, TNFα inhibitors, ACE inhibitors, thrombocyte inhibitors, proton pump inhibitors,
antiepileptics, and NSAIDs [46]. Discontinuation of the offending medication results in gradual diminution of symptoms that may last as long as a year. NSAIDs or low-dose steroids may control the symptoms, and for patients with severe organ system involvement, treatment is similar to idiopathic lupus. Most rheumatologists believe that patients with idiopathic SLE who require hydralazine, procainamide, isoniazid, phenytoin, β-blockers, or other medications that can potentially induce lupus can take these medications. TNFα inhibitors, however, are relatively contraindicated for SLE. It is advisable to document the clinical and serologic status of the patient before starting the medication.
ANTIPHOSPHOLIPID SYNDROME

APS is defined by vascular thrombosis or pregnancy complications in the presence of LA or moderate- to high-titer aPL, documented at least twice, 12 or more weeks apart (Table 66.4). By definition, aPL includes IgG or IgM anticardiolipin antibodies (aCL) and/or anti-β₂ glycoprotein I antibody (anti-β₂ GPI). The LA, aCL, and anti-β₂ GPI all bind to negatively charged phospholipids. How these antibodies induce thrombosis remains unknown, but interaction with endothelial cells, coagulation factors, and platelets, and complement activation all play a role. Thromboses and emboli occur in all vessel sizes and organ systems. Nonthrombotic associations include valvular lesions similar to Libman–Sacks, hemolytic anemia, thrombocytopenia, livedo reticularis, and false-positive tests for syphilis. Primary APS occurs in the absence of other connective tissue disease. When APS is associated with SLE or other connective tissue disorders, it is referred to as secondary APS. Patients with catastrophic APS (CAPS) present with acute multiorgan failure from occlusive vasculopathy of small vessels in the kidney, lungs, brain, heart, adrenal glands, and liver. Large vessel occlusions have also been reported.

TABLE 66.4 Modified Sapporo Classification Criteria for Antiphospholipid Syndrome

</tbody>
</table>

Laboratory criteria (measured at least on two
occasions, 12 weeks apart)
1. Moderate- to high-titer IgM or IgG anticardiolipin antibodies by ELISA
2. Lupus anticoagulant
3. High-titer (>99 percentile) IgM or IgG anti-β₂ glycoprotein I antibody by ELISA

Diagnosis is based on the presence of one clinical and one laboratory criteria. The laboratory finding should not be less than 12 weeks or more than 5 years apart from the clinical event.

The APS manifestations that most likely require ICU admission are cerebrovascular disease, pulmonary embolism, major abdominal or extremity arterial or venous thrombosis, myocardial infarctions, severe valvular disease (insufficiency or thrombotic valvular vegetations), and intracardiac thrombosis. Renal manifestations of APS include hypertension, proteinuria, acute or subacute renal insufficiency, and end-stage renal failure [47]. The classical renal lesion is thrombotic microangiopathy, but the entire renal vasculature can be affected; renal artery lesions can cause renal artery stenosis, cortical ischemia, and infarction, whereas thrombosis of the renal vein and inferior vena cava results in nephrotic range proteinuria. Hemodialysis patients with APS are at increased risk of vascular access thrombosis. CAPS, which occurs in less than 1% of APS, is the most serious and devastating subset, with multisystem small vessel thromboses occurring within a short time period [48]. Differentiation from TTP and DIC is imperative but sometimes difficult because microangiopathic hemolytic anemia or elevated fibrin split products are sometimes present in CAPS. Measurement of ADAMTS-13 activity and anti-ADAMTS-13 and anti-heparin antibodies may help clarify the diagnosis. CAPS precipitating factors include infection, surgery, malignancy, subtherapeutic anticoagulation, and SLE flares. Mortality is high, nearly 48%, with death most often associated with renal, pulmonary, splenic, or adrenal involvement, or underlying SLE [49].

APS patients with venous thrombosis are treated with heparin anticoagulation followed by conversion to warfarin with an INR target of 2.0 to 3.0. Lifelong anticoagulation is supported by a high incidence of recurrent thrombosis when warfarin is discontinued. Moderate-intensity
anticoagulation (INR 2.0 to 3.0) is comparable to high-intensity anticoagulation (INR 3.1 to 4.0) for preventing further venous thromboses and equal in bleeding complications [50]. However, controversy still exists as to whether high-intensity anticoagulation is necessary for patients with arterial clots. Some experts recommend high-intensity warfarin, whereas others recommend moderate-intensity warfarin with or without low-dose aspirin [51]. In APS patients with recurrent thrombosis despite therapeutic anticoagulation, treatment options include standard dose warfarin plus an antiplatelet agent, high-intensity warfarin, unfractionated heparin, or low-molecular-weight heparin. Primary prophylaxis with hydroxychloroquine with or without low-dose aspirin is recommended for patients with SLE and positive LA or persistent moderate- to high-titer aPLs, but there is no evidence to support prophylactic anticoagulation for individuals without SLE who have LA or aPLs in the absence of other thrombotic risk factors [51,52].

Treatment of CAPS requires both anticoagulation and immunosuppressive therapy [51]. Triple therapy with heparin anticoagulation, high-dose corticosteroids, and plasma exchange with or without IVIG has the best survival data [48]. Case reports support the use of RTX (monoclonal antibody to CD20 expressed on B cells) or eculizumab (terminal complement inhibitor) for refractory disease [53,54].
SSc, or scleroderma, is an immune-mediated disease characterized by progressive fibrosis of the vasculature and viscera resulting in end-organ damage of the skin, heart, lungs, kidneys, and gastrointestinal tract. There are two subsets of scleroderma: (a) limited cutaneous disease, often associated with the anticentromere antibody, and (b) systemic/diffuse disease, associated with the presence of antitopoisomerase 1 (SCL-70) or anti-RNA polymerase. Both subsets have potential end-organ complications that result in ICU admission, including severe digital ischemia from RP, respiratory failure, cardiac dysfunction, or renal insufficiency. The following discussion is limited to these areas.

Severe Raynaud’s Phenomenon

Although primary RP is common in the general population (up to 5%), severe secondary RP associated with connective tissue disease often is more difficult to treat, and digital ulceration or gangrene may occur among 25% of SSc patients. Dihydropyridine-type calcium channel blockers (CCBs), usually nifedipine, reduce the frequency and severity of RP attacks and are considered first-line therapy [55]. For patients with an inadequate response to CCBs, sildenafil and other phosphodiesterase-5 inhibitors reduce the frequency and severity of attacks and promote healing of digital ulcers [56]. Bosentan, a dual endothelin receptor antagonist, is effective for reducing the number of new digital ulcers but, although available in Europe, it has not been approved for use in the United States [57]. Topical nitrates, ACE inhibitors, and α-adrenergic receptor blockade are additional therapies with modest benefits. There is increased interest in the use of botulinum toxin, with several small studies showing pain reduction and improved ulcer healing [58]. IV prostacyclin (epoprostenol) or iloprost (a prostacyclin analog) is effective for patients with critical digital ischemia refractory to other therapies (Table 66.5) [59]. Oral prostanoids are less effective. Use of IV prostaglandins should be avoided for patients with pulmonary hypertension unless closely monitored. Chemical digital sympathectomy with lidocaine provides short-term pain relief, and surgical digital sympathectomy can be a last alternative when medical therapies fail.

### Pulmonary Disease

Pulmonary involvement occurs among 25% to 90% of patients with SSc and is now the most frequent cause of death (more than 50%) [60]. ILD and PAH are the two major pulmonary complications of SSc. Patients with diffuse SSc are more likely to develop ILD, whereas isolated PAH is more common in limited scleroderma and patients with anticentromere antibodies, with a prevalence of 12% to 15% [61]. Clinically significant disease from interstitial fibrosis or PAH is estimated to affect 40% of patients (see Table 66.1).

Exertional dyspnea, cough, and basilar crackles are the predominant clinical features of ILD. Radiographs may reveal pulmonary fibrosis among 33% to 40%, with a characteristic basilar reticulonodular or honeycombing pattern [60]. HRCT scans are more sensitive for documenting the reticular and ground glass opacities of ILD when plain radiographs are relatively normal. Pulmonary function tests may reveal restrictive lung disease (decreased total lung capacity and forced vital capacity [FVC]) even before radiographic or clinical findings. A decrease
of diffusing capacity ($D_L^{CO}$) may occur with either ILD or PAH and has been reported in isolation without other pulmonary function test abnormalities. Patients with ILD may develop secondary PAH, but the degree of PAH is disproportionate to the degree of ILD.

Prevention of progressive fibrotic disease is the goal of treatment for SSc-associated ILD. In one study, the extent of disease on CT was predictive of mortality and FVC decline, suggesting that patients with more advanced CT abnormalities should be treated. [62] Patients with less extensive disease should be monitored closely and treated if there is evidence of radiographic progression or decline in pulmonary function. BAL cellularity does not predict disease progression or response to treatment, and currently has a limited role for the evaluation of ILD, but is useful to rule out infection. A randomized, placebo-controlled study of oral cyclophosphamide (1 mg/kg/d titrated to maximum of 2 mg/kg/d) found small but statistically significant improvement in FVC, skin score, and subjective symptoms [63]. Another randomized, placebo-controlled study of IVCY (0.5 to 0.7 g per m$^2$ monthly) demonstrated improvement of FVC [64]. Although there are no controlled trials to compare efficacy of oral versus IVCY, the IV route is most practical initially for the critically ill ICU patient. Low-dose glucocorticoids (equivalent to prednisone 10 mg per day or less) are usually prescribed with CY. Although debate exists as to the benefit of concomitant high-dose prednisone or prednisolone, high-dose glucocorticoids are usually avoided because of the increased risks of infection and scleroderma renal crisis (SRC) and the lack of clinical trial data.

Preliminary results of a large double-blind randomized clinical trial (The Scleroderma Lung Study II) comparing oral CY with MMF suggest that both are effective therapies for SSc ILD, with fewer side effects in the MMF arm [61]. For patients with refractory disease, one small study reported improvement of FVC and $D_L^{CO}$ when RTX was given to patients previously treated with CYC or MMF [65]. Patients with progressive ILD despite medical therapy may be candidates for lung transplantation.

Pulmonary vasospasm and endothelial cell activation with subsequent arterial wall proliferative changes contribute to the development of PAH. Symptoms include exertional dyspnea, fatigue, reduced exercise tolerance, chest pain, syncope, and lower extremity edema, but patients may be asymptomatic until the disease is advanced. The most sensitive tests are decreased diffusing capacity, often with preserved lung volumes, and Doppler echocardiography showing increased pulmonary pressures.
Cardiac Disease

Cardiac involvement of SSc may be a primary process within the heart or secondary to other major organ involvement (i.e., pulmonary, renal, vascular, thyroid). Primary cardiac involvement of SSc includes pericardial disease, myocardial disease, conduction abnormalities, and arrhythmias. Because the most common symptoms are dyspnea, orthopnea, atypical chest pain, palpitations, fatigue, and dizziness, the clinical manifestations of cardiac disease can be confused with those of other organ systemic involvement. Recent studies have also shown an increased burden of atherosclerotic coronary disease with SSc [66].

Pericardial disease is the most common cardiac manifestation, and as in SLE, asymptomatic pericardial disease based on autopsy series or echocardiographic data has a much higher prevalence than symptomatic disease (33% to 71% vs. 7% to 20%). Pericardial effusions are usually small and do not influence prognosis. Larger effusions (>200 mL), however, are associated with a poor prognosis. Pericardial tamponade with hemodynamic compromise is rare. Pericardiocentesis is rarely required unless the patient is hemodynamically compromised or febrile, and an infectious etiology must be excluded. Pericardial fluid tends to be serous with a wide range of leukocyte counts and with normal complement levels. Corticosteroids are rarely required for treatment.

Myocardial involvement is the most common cardiac finding among patients with SSc at autopsy, ranging from 12% to 89%; however, symptomatic disease occurs less frequently than pericarditis. Pathologically, the most common findings are patchy, focal myocardial fibrosis equally distributed in both ventricles and all three layers of the heart [67]. Autonomic cardiac neuropathy may also contribute to the cardiac morbidity of SSc patients.

Clinically, myocardial disease may result in cardiomyopathy, left ventricular diastolic dysfunction, congestive heart failure, angina, conduction abnormalities, or malignant arrhythmias. A high percentage of SSc patients without cardiac symptoms have an abnormal resting ECG,
chest radiograph, Holter monitor, or echocardiogram. Electrophysiologic studies reveal a high incidence of reentrant supraventricular tachyarrhythmias and atrioventricular conduction delays. Ventricular tachycardia occurs among 10% to 13% of patients and is a cause of sudden death. Advanced myocardial fibrosis, rather than selective fibrosis of the conduction system, appears to be responsible for conduction abnormalities and arrhythmias.

Evaluation of acutely ill SSc patients for suspected heart disease should include a routine ECG and chest radiograph. Doppler echocardiography provides information regarding the pericardium, valvular function, systolic and diastolic ventricular function, chamber size, wall thickness, and the presence of pulmonary hypertension. Nuclear scanning may reveal subclinical myocardial disease; cardiac catheterization is useful for accurate assessment of pulmonary arterial pressures but is otherwise unremarkable unless the patient has arteriosclerosis. Negative endomyocardial biopsies cannot exclude myocardial fibrosis because the pathologic process tends to be patchy.

Treatment of SSc cardiac disease is tailored to the specific syndrome. Pericarditis is treated similarly to pericarditis because of other causes with NSAIDs or colchicine. Corticosteroids are generally avoided because of the increased risk of renal crisis, but low-dose corticosteroids can be used in refractory cases. Diuresis should be pursued with caution in patients with large pericardial effusions. Renal failure has been reported among patients after vigorous diuresis, presumably secondary to hypovolemia superimposed on low cardiac output, resulting in decreased renal cortical blood flow. Congestive heart failure is treated as outlined in Chapter 33. However, when echocardiography reveals evidence of diastolic dysfunction, ACE inhibitors or CCBs may be more effective than inotropic agents. A high index of suspicion for coronary artery disease and aggressive management of modifiable risk factors are important aspects of therapy for all patients.

Renal Disease

In addition to cardiac and pulmonary involvement of diffuse scleroderma, significant morbidity and mortality result from renal disease. The onset of accelerated hypertension accompanied by signs of microangiopathic hemolytic anemia, hyperreninemia, and rapidly progressive renal failure describes a syndrome referred to as SRC. SRC may develop among up to 10% of patients with diffuse scleroderma [68]. SRC typically occurs early in the course of the disease for patients with diffuse disease, often in the setting of other organ system involvement. Predictors for development of SRC include high skin score, large joint contractures, tendon friction rubs, prednisone use, and anti-RNA
polymerase III antibodies [68].

Although the pathophysiology of SRC is unknown, several factors contribute to its evolution. The primary event is endothelial cell injury, leading to intimal proliferation and luminal narrowing. Combined with other contributing factors such as vasospasm, decreased renal blood flow leads to increased renin release and clinical development of malignant hypertension and SRC. Moderate- to high-dose corticosteroid use is associated with the development of SRC, possibly because of the inhibition of prostacyclin production.

The diagnosis of SRC should be strongly considered in the SSc patient with accelerated hypertension, although SRC may occur rarely in normotensive patients. In addition to accelerated hypertension, proposed diagnostic criteria also include increase in serum creatinine >50% over baseline, proteinuria, hematuria, thrombocytopenia, hemolytic anemia, and hypertensive encephalopathy [68].

Since the advent of aggressive management with ACE inhibitors, conservation or improvement of renal function is possible. It is now clear that this class of drugs is the standard of care for SRC. Short-acting ACE inhibitors should be titrated upward every 6 to 12 hours. Blood pressure should be controlled within 48 hours. Additional antihypertensives, including CCBs, can be added. For many patients treated with ACE inhibitors, there may be a transient reduction in glomerular filtration rate and a rise in serum creatinine.

Although ACE inhibitors have markedly improved outcomes in SRC, 1-year mortality is as high as 36%, and 25% remain on dialysis 1 year after SRC onset [69]. Survival data of patients with good outcomes (not requiring dialysis) after SRC are similar to those of SSc patients without renal crisis. For patients with good outcomes after the initial renal crisis, continuing ACE inhibitors indefinitely may provide further benefit to maintain renal function. There is no evidence to support the use of ACE inhibitors for primary prevention of SRC. In fact, exposure to ACE inhibitors prior to onset of SRC is associated with a twofold increased risk of mortality [69].

Gastrointestinal Disease
Gastrointestinal tract involvement is common among SSc, affecting 50% to 80% of patients. The most common physiologic abnormalities, esophageal dysmotility and decreased lower esophageal sphincter pressure, are manifested by symptoms of dysphagia and heartburn,
respectively. Impaired microvascular perfusion initially alters myoelectrical function of the smooth muscle layer and results in fibrotic changes in muscularis, submucosa, and lamina propria [70]. Dysphagia and heartburn are treated symptomatically with prokinetic agents (metoclopramide and macrolide antibiotics) and proton pump inhibitors. Serious complications include strictures and Barrett’s esophagus.

Gastric involvement is less common but can include gastroparesis and bleeding. Gastroparesis, with symptoms of early satiety, bloating, and vomiting, can lead to malnutrition. Treatment of gastroparesis includes dietary modification, antiemetics, and prokinetic agents. Telangiectasias are a common source of gastrointestinal blood loss. Gastric antral vascular ectasia (GAVE), or “watermelon stomach,” may present with acute bleeding and antedate the diagnosis of SSc. Telangiectasias and GAVE are managed with endoscopic coagulation. Partial or total gastrectomy may be required for refractory disease. Supportive measures include iron supplements, blood transfusions, and proton pump inhibitors. Case reports suggest that IVCY is an effective treatment for refractory GAVE [71].

Small and large intestinal involvement usually occurs concomitantly and results in malabsorption, with symptoms of bloating, cramping, and intermittent or severe diarrhea. Hypomotility due to progressive smooth muscle atrophy and fibrosis results in bacterial overgrowth. In addition, adynamic ileus or pseudo-obstruction may occur. Although barium studies reveal wide-mouth sacculations or diverticula on the antimesenteric border, most patients have relatively few symptoms. Fecal incontinence and constipation are common but underreported. Rare complications include obstruction because of fecal impaction, megacolon, and volvulus. Pneumatosis cystoides intestinalis (PCI), or intramural air-filled cysts in the small or large intestines, may be found incidentally or cause abdominal pain, diarrhea, or bloody rectal discharge. Rupture of these cysts results in pneumoperitoneum without peritonitis.

Prokinetic agents have been reported to be useful for treatment of intestinal disease. Intestinal malabsorption has been treated with antibiotics, low-residue diets, medium-chain triglycerides, fat-soluble vitamins, and total parenteral nutrition. Octreotide improves intestinal peristalsis for pseudo-obstruction and, in combination with erythromycin, may have additive benefits [72]. An investigational 5-HT4 receptor agonist, prucalopride, improves symptoms and gut transport in SSc [73]. Prucalopride is approved for use in Europe, but is not yet available in the United States. Cisapride, another 5-HT4 receptor agonist, is severely restricted in the United States because of concerns regarding severe cardiac arrhythmias. PCI is usually managed conservatively without surgery. Malabsorption and PCI are poor prognostic indicators [74].
Primary biliary cirrhosis (PBC) is the most common liver disease associated with SSc. Up to 18% of patients with PBC have SSc, usually the limited cutaneous form, whereas 8% of all SSc patients have antimitochondrial antibodies. PBC most often follows the diagnosis of SSc, but can be the presenting symptom.
IDIOPATHIC INFLAMMATORY MYOPATHIES

Polymyositis (PM), dermatomyositis (DM), inclusion body myositis (IBM), and immune-mediated necrotizing myopathy (IMNM) are the most common acquired inflammatory myopathies, characterized by progressive muscle weakness and elevated muscle enzymes, and some are associated with other organ system involvement. Each subtype also has unique clinical, histologic, and autoantibody features (Table 66.6 provides summary of these features).

ᵃUnless related connective tissue disease such as systemic sclerosis, mixed connective disease.
ᵇAssociated with amyopathic DM or rapidly progressive interstitial lung disease.
ᶜAssociated with typical rash of DM.
ᵈCancer-associated DM.
In both PM and DM, other organ system involvement is common. Skin involvement is the most visible characteristic finding in DM, with classic findings that may include: heliotrope rash (erythema or violaceous changes on the upper eyelids), Gottron’s papules (scaly erythematous patches) overlying the MCP and PIP joints, Gottron’s sign (similar to Gottron’s papules but located on the extensor surfaces of the knees and elbows), erythema or papules typically in a V shape and mantle distribution on the neck and chest, or scaly lesions in the scalp. “Mechanic’s hands” (rough, scaly, cracked lesions in the palm or lateral aspects of the fingers), however, can be found in both DM and PM associated with antisynthetase syndrome. Otherwise, PM and IBM have no skin manifestations, whereas IMNM may have associated skin features if related to SSc or mixed connective tissue disease (MCTD). Both PM and DM may have pulmonary, cardiac, or gastrointestinal involvement (see below).

IBM, however, differs from PM/DM in that age of onset is older and the course is more indolent. Muscle involvement includes distal muscles more than proximal, facial muscles, often in an asymmetric pattern. Atrophy of quadriceps, forearm, or intrinsic hand muscles can be present. Creatine kinase (CK) is often only mildly elevated, and other organ system involvement is rare.

IMNM is characterized by severe proximal muscle weakness, sometimes accompanied by myalgias. IMNM can be idiopathic, associated with statin use, viral infections such as HIV or hepatitis C, scleroderma or MCTD, or malignancies such as adenocarcinoma of colon or lung cancers (both small and non–small cell). Symptom onset is usually subacute but can be acute, and CKs are highly elevated. Other organ systems are rarely involved except the subgroup associated with anti–signal recognition particles (SRPs). Those patients may have ILD, Raynaud’s, or dysphagia. If the myositis is associated with connective tissue diseases such as scleroderma, then other organ system involvement can occur [75]. Diagnosis of this subgroup is based on characteristic histopathology and autoantibody profile (see below).

The diagnosis of PM/DM, IBM, and IMNM is based on characteristic clinical, electromyographic, histopathologic, and autoantibody profiles. Other causes of myopathy or myositis need to be excluded. Creatine kinase is elevated anywhere from 10 to 50 times normal, but rhabdomyolysis is rare. Electromyography will identify muscles involved and distinguish myopathic features from neurogenic causes, but it will not be able to differentiate the different types of inflammatory myopathies, or even from toxin-related causes or dystrophies. Muscle biopsy may not be required with classic DM features of skin lesions, proximal muscle weakness, and elevated CPKs. However, for any other presentation that is not classic for DM, a muscle biopsy is important to
establish the diagnosis and exclude other causes of muscle weakness (including PM/IBM or IMNM). The biopsy should be taken from a muscle that is affected clinically, usually the quadriceps or deltoid. T2-weighted MRI with fat suppression is useful for identifying an actively inflamed muscle for biopsy. Histopathology of DM is characterized by vascular process with perifascicular atrophy because of inflammation of the perivascular areas, and deposition of aggregates of complement (membrane attack complex) on endothelial cell wall of endomysial. PM and IBM biopsies, however, reveal inflammation of the perivascular areas and within the endomysium, that is, CD8\(^+\) T cell dominant. Inflammatory cells are throughout the normal muscle fibers and fascicles. IBM also has characteristics of inflammatory cells in non-necrotic muscle fibers and presence of rimmed vacuoles, ragged fibers, and inclusion bodies on electron microscopy. In contrast, IMNM histology will reveal the same findings of necrosis as in PM, but only few inflammatory cell infiltrates in the muscle fibers. There may be presence of major histocompatibility complex (MHC) class I expression on noninvolved muscle fibers.

A number of myositis-specific antibodies and myositis-associated antibodies have been identified that correlate with specific clinical presentations and may help with diagnostic and prognostic information [76] Anti-Mi-2, found in up to 10% of patients with myositis, is associated with classic DM, and is a marker for a more favorable prognosis. The presence of anti–histidyl transfer RNA synthetase (anti-Jo-1) or antimelanoma differentiation–associated protein-5 (anti-MDA-5) antibodies is strongly associated with significant ILD (up to 70%) [76]. Antibodies against SRP occur in only 5% of myositis patients, but are associated with acute, severe myositis including IMNM with an overall poor prognosis. Anti–3-hydroxy-3-methylglutaryl-coenzyme A reductase is present among patients who had prior exposure to statins (although some have not), and, despite discontinuation, continue to have severe IMNM. Antitranscriptional intermediary factor 1γ (anti-TIF-1γ) is seen with cancer-associated DM. Table 66.6 summarizes the various clinical, laboratory, histopathologic, and serologic features of these idiopathic inflammatory myopathies.

Inflammatory myositis is also associated with inborn errors of metabolism, lipid storage disease, and mitochondrial myopathies, but
these will not be discussed here. Numerous drugs can cause myopathy or myositis that is sometimes difficult to distinguish from inflammatory myositis. These drugs include lipid-lowering agents, glucocorticoids, antipsychotics, antimalarials, colchicine, nucleoside reverse transcriptase inhibitors, alcohol, and cocaine. Bacterial infections (*S. aureus, Streptococcus pyogenes, Clostridium perfringens, Borrelia burgdorferi*) and viruses (cox sackievirus A and B, echovirus, influenza A and B, adenovirus 2 and 21, hepatitis B and C, and HIV) can cause a myopathy that may be confused with PM or DM. Parasites including trichinopathy, toxoplasmosis, cysticercosis, toxocariasis, and amebiasis may all cause myositis. Muscular dystrophies, neuropathic disease, and metabolic/endocrine diseases also need to be excluded in patients with muscle weakness.

PM and DM are primarily disorders of skeletal muscle, but involvement of the pulmonary, cardiac, articular, gastrointestinal, or vascular systems sometimes leads to catastrophic illness requiring support in an ICU. Moreover, organ dysfunction may occur among patients with overlap syndromes. Respiratory failure, cardiac abnormalities, or comorbidities related to immunosuppression are the most common reasons for ICU admission. A complete discussion of the presentation, diagnosis, management, and differential diagnosis is beyond the scope of this chapter, but excellent reviews exist [76,77].

**Pulmonary Involvement**

Lung disease in PM/DM patients is common (10% to 40% of patients; see Table 66.1) and includes (a) respiratory insufficiency because of weakness of intercostal or diaphragmatic muscles; (b) aspiration pneumonia; (c) pneumonia from either bacterial, viral, or opportunistic infection; and (d) ILD. Pulmonary vasculitis, pleuritis, pulmonary edema, alveolar hemorrhage, secondary pulmonary hypertension, and OP have also been reported but are uncommon. Dyspnea, cough, and chest pain are the usual symptoms.

Respiratory failure from intercostal muscle weakness or diaphragmatic dysfunction occurs among 7% of PM/DM patients. Thus, pulmonary mechanics (spirometry, inspiratory force) should be evaluated when respiratory symptoms develop. Serial measurements often predict impending respiratory failure that might necessitate intubation and mechanical ventilation. Management of respiratory failure resulting from muscle weakness is supportive (oxygen, mechanical ventilation) and accompanied by therapy directed at the underlying myositis (see Chapter 165).

Bronchopneumonia occurs among up to 24% of PM/DM patients. Contributing factors include pharyngeal incompetence and poor airway
protection with subsequent aspiration, iatrogenic immunosuppression, and often a weakened cough. Infectious agents include virulent bacteria and opportunistic organisms. Myositis occurring in the setting of acquired immunodeficiency further expands the possible spectrum of infectious agents. Hence, respiratory symptoms should be evaluated aggressively with chest radiographs and routine and specialized microbiologic techniques (culture for bacteria, mycobacteria, fungi, and smears for *Pneumocystis jiroveci*).

The most common type of parenchymal lung disease in PM/DM is ILD, with a prevalence of 20% to 60%. Patients develop progressive dyspnea with or without a nonproductive cough and bibasilar rales. Pulmonary function tests reveal decreased lung volumes and reduced diffusing capacity. Ground glass opacities, reticulonodular infiltrates, or patchy consolidations may be present on HRCT scans and suggest possible diagnoses. However, histopathology is necessary to diagnose NSIP, UIP, OP, or, less commonly, acute interstitial pneumonia. Patients with Jo-1 and other anti-aminoacyl-tRNA synthetase antibodies have a high incidence of ILD and also described as antisynthetase syndrome that is characterized by prominent arthritis, fever, RP, and mechanic’s hands. Fulminant ILD has occurred in amyopathic DM without anti-Jo antibodies but rather with anti-MDA-5.

**Myocardial Involvement**

Cardiac and pulmonary diseases along with cancer are the main prognostic factors for PM/DM mortality [78]. Up to 70% of patients have cardiac abnormalities on noninvasive testing, but clinically, only less than 10% are symptomatic. However, it is estimated that cardiac disease is the cause of 10% to 20% of deaths in patients with myositis [79]. Myocarditis may manifest as heart failure, arrhythmias, cardiac arrest, or myocardial infarction. It is difficult to diagnose because levels of creatine kinase and muscle brain fractions are elevated as a result of skeletal muscle inflammation. Cardiac troponin I is the most specific marker for myocardial involvement. Cardiac imaging techniques (echocardiogram, gallium citrate- or indium-labeled antimyosin antibody detection, and scintigraphic studies) are insensitive and nonspecific for detecting myocardial involvement. Contrast-enhanced cardiac MRI provides a more sensitive way to differentiate myocarditis from myocardial ischemia.

The extent to which any cardiac abnormality is iatrogenic or arises as a complication of the disease is unclear. For example, steroid therapy accelerates atherosclerosis and may exacerbate hypertension, diabetes mellitus, and electrolyte disturbances. Similarly, hypoxia from pulmonary involvement contributes to arrhythmias, axis shifts, and strain patterns
on ECG. However, DM and PM patients have three to fourfold higher risk for myocardial infarction than controls matched for age and other risk factors.

Other Organ System Involvement

The major gastrointestinal manifestation of inflammatory myopathies is weakness of the upper pharyngeal striated muscles, resulting in dysphonia, dysphagia, and regurgitation of fluids. Smooth muscle involvement of the distal esophagus is rare, and intestinal vasculitis, commonly seen in childhood DM, is also uncommon. Renal failure and its attendant metabolic abnormalities are the result of rhabdomyolysis, myoglobinemia, and subsequent myoglobinuria. Myoglobinuric renal failure is rare, but tends to occur in patients with acute or hyperacute presentations as a result of widespread muscle necrosis and release of sarcoplasmic materials, including myoglobin. Therapy is directed toward the underlying muscle disease while maintaining an adequate urinary output.

Malignancy

The relationship of PM/DM to malignancy has been established by multiple epidemiologic studies from different countries. A meta-analysis recently of all studies up to 2013 confirmed that DM is associated with the highest risk with pooled rate ratio (RR) of 5.5, while PM RR was around 1.6 [80]. The diagnosis of malignancy may precede, be concurrent with, or follow the onset of myositis. The risk decreases with time, but even at 5 years, the risk is still measurable. Identified risk factors include later age at diagnosis, cutaneous necrosis and leukocytoclastic vasculitis, capillary damage on muscle biopsy, and dysphagia. Malignancies commonly associated with DM/PM include breast, ovarian, lung, colon, gastric, pancreatic, nasopharyngeal, and non-Hodgkin’s lymphoma. Two myositis-specific antibodies have been associated with malignancy: anti-TIF-1γ and anti-nuclear matrix protein 2 (anti-NXP-2).

Treatment

High-dose corticosteroids are the first-line therapy for PM/DM and IMNM, although there are no published clinical trials to support this approach at this time. Initial treatment is usually with prednisone 1 to 1.5 mg/kg/d for 6 to 8 weeks, then tapered based on clinical response. In
more severe cases (dysphagia, alveolitis, myocarditis, or impending respiratory failure from muscle weakness), IV methylprednisolone may be given at a dose of 1,000 mg daily for 3 days followed by the usual high-dose oral corticosteroid regimen. In steroid-responsive patients, a steroid-sparing agent (methotrexate, AZA, MMF, cyclophosphamide, or calcineurin inhibitors) may be added to facilitate steroid tapering, but efficacy is based on small case series or clinical experience as no randomized clinical trials have been done. Therapy for progressive or severe ILD usually requires the use of corticosteroids and cyclophosphamide. Ciclosporine or tacrolimus can be used for refractory cases [81]. Although a placebo-controlled trial of RTX, given either early or late to PM or DM patients unresponsive to steroids or alternative agents, did not show statistically significant differences of disease response, nearly 80% of all patients had improvement and suggested efficacy [81]. IVIG is recommended for patients with severe weakness refractory to steroids based on proven efficacy in a randomized, placebo-controlled trial in patients with DM [82].

Therapy for IBM is more difficult because it responds to steroids poorly and slowly. IVIG and methotrexate have not been effective in double-blind, placebo-controlled trials. Current recommendations include a trial of steroids if muscle biopsies reveal significant inflammation and physical therapy to help maintain strength and function.

Advances in management of rheumatologic diseases, based on randomized controlled trials or meta-analysis of published studies, are summarized in Table 66.7.

Vasculitis in the Intensive Care Unit

PAUL F. DELLARIPA • DONOUGH HOWARD

The vasculitides are a group of disorders characterized by the presence of destructive inflammation in vessel walls [1–4]. The possibility of systemic vasculitis should be considered for a patient with systemic complaints and dysfunction of multiple organ systems, frequently in the context of constitutional symptoms such as fever, malaise, and weight loss (Table 67.1). Patients hospitalized in the intensive care unit (ICU) may present with symptoms related to the clinical features associated with a specific vasculitis but may also present with a known diagnosis of vasculitis and complications of treatment, most notably infection.

Vasculitic syndromes typically are classified by the size of vessel involved. Although there may be an overlap in the vessel size, diseases may affect predominantly large vessels (Takayasu’s arteritis), medium-size arteries (such as polyarteritis nodosa (PAN) and central nervous system [CNS] vasculitis), and small vessels (granulomatosis with polyangiitis [GPA], formerly known as Wegener’s granulomatosis; microscopic polyangiitis; eosinophilic granulomatosis with polyangiitis [EGPA], also known as Churg–Strauss syndrome; cryoglobulinemia; and drug-induced vasculitis). These particular vasculitides are the focus of this chapter. For a more general discussion of vasculitis, other references are noted [1–4].

Disorders not discussed but that may simulate presentation of vasculitis include embolism due to endocarditis; cardiac myxoma; hypercoagulable states including the antiphospholipid antibody syndrome, hyperviscosity syndromes, chronic ergotism, radiation arteriopathy; and, less commonly, Ehlers–Danlos syndrome, neurofibromatosis, Sweet’s syndrome, pseudoxanthoma elasticum, and Köhlmeier–Danlos diseases [5,6].

POLYARTERITIS NODOSA

PAN is a systemic necrotizing arteritis involving predominantly medium-size vessels, although sometimes affecting smaller vessels. Vasculitic lesions characteristically occur at the bifurcations or branches of vessels and are often segmental. Almost any organ can be involved, but frequently the skin, peripheral nerves, kidneys, gastrointestinal (GI) tract, and joints are the principal organs affected [7].

Clinical manifestations include malaise; weight loss; fevers, abdominal or lower-extremity pain; myalgias; or arthralgias. Clinical parameters include hypertension and azotemia with proteinuria but rarely glomerulonephritis. Peripheral neuropathy occurs in up to 60% of cases, usually involving a mixed sensorimotor and mononeuritis multiplex [8]. Sudden-onset paresthesias associated with motor deficits are common manifestations. CNS involvement, including seizures, focal events, and
altered mental status, are less common [9]. Musculoskeletal symptoms including arthralgias (50%), and less frequently, arthritis can occur [7]. Vasculitis of skeletal muscles may cause severe myalgias, and muscle biopsy can be useful diagnostically [10]. Abdominal pain may have a variety of causes, including intestinal angina; mesenteric thrombosis; and localized gallbladder or liver disease. Acute GI bleeding, perforation, and infarction are rare but are associated with a high mortality if the diagnosis is not established promptly [11]. Cardiac involvement, observed in nearly 60% of autopsy series, is often clinically silent and includes congestive heart failure, pericarditis, myocardial infarctions, and conduction abnormalities [12,13]. Cutaneous lesions include nonspecific palpable purpura, livedo reticularis, tender nodular lesions, digital infarcts, and ulcers [14]. Arteritis of the eye, testes, pancreas, ovaries, breasts, and involvement of the temporal arteries may develop rarely.

The pathogenesis of polyarteritis is unknown. Hepatitis B surface antigen has been found in a minority of patients with PAN. The presence of circulating immune complexes of hepatitis B surface antigen and deposition of surface antigen and immunoglobulin in vessel walls has suggested that immune mechanisms may play a role in some forms of polyarteritis [15,16]. Hepatitis C has rarely been associated with PAN [17]. Pathologically, fibrinoid necrosis and pleomorphic cellular infiltration, predominantly with lymphocytes, macrophages, and varying degrees of polymorphonuclear leukocytes involve the entire wall of small and medium muscular arteries. Thromboses and aneurysms can be found in lesions [18]. Laboratory abnormalities of PAN usually include elevated sedimentation rate, elevated C-reactive protein (CRP), and thrombocytosis. Antineutrophil cytoplasmic antibody (ANCA), antinuclear antibody (ANA), and rheumatoid factor are not typically present in PAN. Mesenteric angiography often shows evidence of aneurysms including the renal, hepatic, and mesenteric arteries, and areas of arterial stenosis alternating with normal or dilated vessels [18]. Sural nerve biopsies are easily accessible sources of nerve tissue when a mononeuritis is present, although the location of biopsy may be guided by electromyography.

Although there is no consensus for treatment of PAN, administration of corticosteroids at 1 mg/kg/d orally is indicated in nearly all cases where there is moderate to severe disease which is defined as the presence of active renal, GI, neurologic, or cardiac disease. In fulminant disease, daily intravenous (IV) methylprednisolone, 1 g/day for 3 days, is reasonable followed by daily oral or intravenous corticosteroids. In the presence of
GI involvement, intravenous dosing may need to be continued especially for life-threatening cases. The use of a second drug is guided by the severity of presentation and if there is failure to respond to steroids alone. One prospective trial amongst several retrospective cohorts suggests that those with more severe illness benefit from the use of cyclophosphamide in combination with corticosteroids [19]. Cyclophosphamide may be given orally, usually 2 mg/kg/d, though adjustment should be made for renal failure (Table 67.2), or by intravenous dosing of 500 to 1,000 mg/m² monthly (see Table 67.3 on Immunomodulation), or using the IV regimen similar to treatment of GPA (see below). Plasmapheresis in combination with antiviral therapy may be beneficial in hepatitis B-associated PAN [20,21].

A variety of drugs, viral infections, connective tissue diseases such as rheumatoid arthritis, and underlying malignancies may cause a necrotizing angiitis that may be indistinguishable from polyarteritis
[22–27].
MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis is a necrotizing vasculitis that involves small vessels, including arterioles, capillaries, and venules. Clinical presentations may involve concomitant capillaritis with or without alveolar hemorrhage and rapidly progressive glomerulonephritis, the so-called pulmonary renal syndrome, although more indolent and slower presentations have been described. Glomerulonephritis occurs in nearly all cases, and pulmonary involvement ranging from cough and dyspnea to frank hemoptysis occurs in up to 30% of cases. Neuropathy and cutaneous vasculitis occur in up to 50% of cases. ANCA is found in about 75% of cases, mostly specific for myeloperoxidase (MPO), though occasionally ANCA proteinase 3 (PR3) has been described [14,26,27].

Diagnosis is typically made with a biopsy of lung, kidney, skin, or nerve in conjunction with a positive ANCA result. Most clinical trials for treatment of ANCA associated vasculitis included both GPA and microscopic PAN. Thus, treatment is identical with corticosteroids at 1 mg/kg/d oral or intravenous methylprednisolone, and intravenous rituximab or cyclophosphamide given orally or intravenously [27–29] (Please refer to following section on treatment of GPA for details). PE may have a role in the treatment of severe renal disease with evidence suggesting a lower frequency of dialysis, but no mortality benefit [30]. There are no prospective data available regarding the efficacy of plasmapheresis in diffuse alveolar hemorrhage (DAH), although retrospective data suggest a benefit [31]. In the face of DAH and severe respiratory failure in the setting of a systemic vasculitis, plasmapheresis in addition to corticosteroids and rituximab or cyclophosphamide is reasonable as long as every effort has been made to exclude infection. In relapsing disease, intravenous immunoglobulin may be of benefit [32].

Eosinophilic Granulomatosis with Polyangiitis (Churg–Strauss Syndrome)

EGPA, formerly Churg–Strauss syndrome (CSS) is characterized by the presence of eosinophilic infiltrates and granulomas in the respiratory tract and necrotizing vasculitis in the setting of asthma and peripheral eosinophilia. Typically, patients have a preceding history of asthma and allergic rhinitis and then develop constitutional symptoms of fatigue and weight loss followed by systemic symptoms such as mononeuritis multiplex, cardiomyopathy, pulmonary infiltrates, or abdominal pain [14]. Pulmonary disease includes fleeting or diffuse infiltrates and nodular lesions [33]. The diagnosis of eosinophilic pneumonia may be
suggested in the context of peripheral infiltrates and peripheral eosinophilia. Rarely alveolar hemorrhage may occur. Peripheral neuropathy occurs in up to 75% of patients with EGPA, whereas renal involvement is much less common than in microscopic polyangiitis and GPA. Other sources of morbidity and mortality include GI involvement with bleeding and bowel perforation, cardiac involvement causing arrhythmias, myocarditis, pericarditis, and congestive heart failure [33,34]. The etiology of EGPA is unknown. ANCA is positive in approximately 38% to 60% of cases, mostly myeloperoxidase [35–37]. Distinguishing between EGPA and other types of hypereosinophilic syndromes can be a challenge clinically. Corticosteroids alone in high doses are effective treatment though with severe organ involvement other agents such as cyclophosphamide are utilized [19]. Case reports suggest rituximab may be effective in severe cases of EGPA.
CRYOGLOBULINEMIC VASCULITIS

Cryoglobulins are immunoglobulins that precipitate below 37°C. There are three types: Type I, seen in myeloproliferative disorders; type II, or mixed essential cryoglobulins; and type III, mixed polyclonal. Types II and III are most closely associated with hepatitis C infection. Typical involvement includes cutaneous vasculitis, arthritis, and peripheral neuropathy. Abnormal liver enzymes suggest hepatitis C infection; complement levels, especially C4, are decreased [38,39]. Infrequently, cryoglobulinemic vasculitis may be life threatening with severe renal, GI, and pulmonary involvement including alveolar hemorrhage [40,41].

Therapy in severe cases consists of corticosteroids and rituximab or less frequently cyclophosphamide in conjunction with antiviral therapy for those that are related to hepatitis C, with careful attention to the potential risk of increased hepatitis C replication [42]. For severe cases involving progressive glomerulonephritis, plasmapheresis or cryofiltration may be of additional benefit [43–45].

Granulomatosis with Polyangiitis

GPA, formerly Wegener’s granulomatosis, is a disease of unknown etiology characterized by granulomatous vasculitis of the upper and lower respiratory tract, segmental necrotizing glomerulonephritis, and systemic vasculitis of small blood vessels [46]. A subset of patients may have disease isolated to the upper respiratory tract or have less severe organ involvement and are referred to as having “limited” GPA [47,48]. Patients most frequently require intensive care treatment for severe pneumonitis; glomerulonephritis; stroke; myocardial infarction; multiorgan system dysfunction secondary to necrotizing vasculitis; and infection due to immunosuppression and anatomic abnormalities secondary to the granulomatous inflammation.

The etiology of GPA is unknown. Possible infectious etiologic associations with Staphylococcus aureus have been proposed but are as yet unproven [49]. ANCA is present in more than 90% of patients with systemic GPA and in 70% to 80% with active limited disease. In GPA, the pattern noted on immunofluorescence is C-ANCA or cytoplasmic staining, and the specific antigen in most cases is the PR3 antigen, although in 10% of cases or more, there may be a P-ANCA or perinuclear staining with MPO (myeloperoxidase) as the specific antigen [50]. Correlation of ANCA titers with clinical remission is controversial, with the most recent data suggesting that relapse is unlikely in treated patients with negative titers, whereas those with rising or recurrently positive
titers have a higher risk of relapse, although the timing of relapse is not predictable [51–53]. The pathology of vasculitis includes fibrinoid necrosis with inflammatory mononuclear cell infiltrates of vessel walls, focal destruction of the elastic lamina, and narrowing or obliteration of vessel lumens. Granulomatous lesions are characterized by areas of central necrosis surrounded by epithelial fibroblasts and scattered multinucleated giant cells [54]. Granulomatous vasculitis may involve the lung, skin, CNS, peripheral nerves, heart, and other organs.

Most patients present with symptoms referable to the upper respiratory tract, including sinusitis, nasal obstruction, rhinitis, otitis, hearing loss, ear pain, gingival inflammation, epistaxis, sore throat, laryngitis, and nasal septal deformity. Fever, in addition to being caused by the underlying disease, may be due to suppurative otitis or *S. aureus* sinusitis [55]. Granulomatous vasculitis of the upper respiratory tract may lead to damage of nasal cartilage, resulting in the “saddle-nose” deformity; sore throat; and oral and nasal mucosal ulcers [56]. In addition, chondritis of the nose or ear may develop [57]. Laryngeal involvement may result in severe narrowing of the upper respiratory tract [58–60]. Unusual manifestations of GPA include distinctive punched-out ulcerative skin lesions appearing as pyoderma gangrenosum and painless subcutaneous nodules [61].

Although only one third of patients present with symptomatic lung involvement (including cough, sputum production, dyspnea, chest pain, hemoptysis, and even life-threatening pulmonary hemorrhage), lower respiratory tract disease is found in almost all patients after evaluation. The characteristic chest radiographic findings are multiple, nodular, bilateral cavitary infiltrates, but infiltrates without sharp margins occur more frequently than distinct nodules. Cavitation may occur in distinct nodules and in infiltrates with less-defined borders. Nodules may have thick or thin walls. Infiltrates may involve the lower or upper lobes. In approximately 50% of patients, the infiltrates are bilateral. Infiltrates may be transient [60,62]. Less common chest radiographic abnormalities include paratracheal masses, large cavitary lesions, a miliary pattern, massive pleural effusion, calcified nodule, and masses between the trachea and esophagus [63]. GPA may also be associated with inflammation and subsequent scarring/stenosis of the subglottic region, in about 25% of patients [64]. This complication is distinctly more common in younger adult and pediatric populations and may sometimes be difficult to differentiate from relapsing polychondritis where tracheal and subglottic inflammation is the major presenting feature.

Although renal manifestations are often asymptomatic, urinalysis reveals renal involvement among approximately 80% of patients at presentation. The typical renal lesion is segmental necrotizing glomerulonephritis. Functional renal impairment may progress rapidly if
appropriate therapy is not instituted promptly [65,66].

The vasculitis of GPA may cause a variety of other clinical manifestations, including arthralgias and less commonly arthritis, most frequently affecting the knees [67,68]; perinephric hematoma; renal artery aneurysms; ureteral obstruction [69]; a variety of cutaneous lesions, including ulcers, papules, vesicles, and subcutaneous nodules [62]; episcleritis; conjunctivitis; scleritis; uveitis; optic nerve vasculitis [70]; mononeuritis multiplex or polyneuritis; cranial nerve dysfunction; meningitis [71]; cerebral infarction [72]; subarachnoid hemorrhage; abdominal pain; intestinal perforation; and diarrhea [73].

Typically, diagnosis is based on the clinical findings of upper and lower respiratory tract noninfectious inflammation [74] with glomerulonephritis and positive anti-PR3 antibodies and rarely MPO antibodies. For cases with more limited involvement or where ANCA titers are negative or show the less typical MPO specificity, tissue diagnosis may be necessary.

Treatment of GPA have led to the development of a biphasic approach with an initial remission–induction phase using either rituximab or cyclophosphamide in combination with corticosteroids until remission (usually within 3 to 6 months) followed by a remission–maintenance phase using a less toxic immunosuppressive agent, usually methotrexate, azathioprine, or mycophenolate, or continued dosing of rituximab [28,75,76]. At this time, experts in the field are divided on the preferential use of one drug over the other for induction. However, there may be other factors such as fertility concerns, a risk of malignancy, or other issues that favor rituximab as the initial option. In selected patients with early and less severe disease, methotrexate may be used for induction though with a higher risk of relapse [77].

Initial treatment with corticosteroid is generally given as prednisone 1 mg/kg/d orally. For the critically ill patient with severe systemic involvement, pulse corticosteroid with IV methylprednisolone 1 g/day for 3 days is advocated, transitioning to prednisone 1 mg/kg/d orally or its IV equivalent. Prednisone therapy is maintained at 60 mg for 1 month and then weaned to 20 mg over 2 to 3 months and then slowly tapered thereafter.

Two randomized trials explore the efficacy and safety of rituximab versus cyclophosphamide (one study with intravenous dosing and the second with oral dosing) as induction therapy for ANCA-associated vasculitis. The results of both studies suggest equivalency for inducing remission and also similar adverse event profile [29,78]. The precise role
of rituximab for rapidly progressive ANCA vasculitis of the critically ill patient (i.e., severe renal failure or pulmonary hemorrhage) is unknown because this was not the focus of the two prospective trials utilizing this agent. Patients should be screened for past exposure to hepatitis B as rituximab can cause fulminant reactivation of latent hepatitis B.

Cyclophosphamide can be administered as intravenous boluses or as a daily oral dose. Both approaches have shown similar rates of remission—induction at 6 months, 78% with daily oral treatment versus 89% with monthly IV boluses [79]. However, relapse rates were much higher among the IV group, 52% compared with 18% in the daily oral group. Follow-up of this group after a mean of 4.3 years revealed that despite the higher relapse rate of the IV group, renal morbidity and overall mortality was equal. The cumulative dose of cyclophosphamide of the IV group was about 50% less than that of the oral group and leukopenia was less frequent. Development of malignancies was not different but the duration of study was likely not long enough to detect changes.

For the clinically ill patient, initial treatment should be with IV cyclophosphamide. One regimen starts with cyclophosphamide 15 mg/kg (maximum dose: 1,200 mg) every 2 weeks for three doses, followed by continued pulses of either 15 mg/kg IV (maximum dose: 1,200 mg) every 3 weeks or 2.5 to 5 mg/kg/d orally on days 1, 2, and 3 every 3 weeks until remission has been achieved and then continued for additional 3 months after remission [79]. Another similar regimen recommends 0.5g/m2 every 2 weeks for 3 to 6 months until remission. The dose can be increased to 0.75 g/m2 or lowered based on nadir WBC and absolute neutrophil count. If the oral regimen is chosen, the dose is 2 mg/kg/d in single am dose until remission and then dosing may be decreased to 1.5 mg/kg daily for additional 3 months [79]. Both oral and intravenous doses need to be adjusted for renal impairment. Table 67.2 outlines the renal adjustments in oral cyclophosphamide doses. Although the dosing regimen for IV cyclophosphamide differs for GPA and SLE, Table 68.2, which outlines a standard protocol for the use of monthly IV cyclophosphamide for SLE, provides guidelines on hydration, antiemetics, dose reduction for renal impairment, and the use of MESNA to prevent bladder toxicities.

Cyclophosphamide therapy is associated with significant morbidity including a 2.4-fold increase of malignancy with 11-fold increase in the risk of leukemia or lymphoma and a significant increased risk of bladder cancer occurring in 1% to 3% of GPA patients treated with cyclophosphamide [80]. Hemorrhage cystitis has been reported in 12% to 43% of patients treated for GPA. In one NIH study, 57% of women of childbearing years became infertile [80]. Opportunistic infection, particularly with *Pneumocystis jiroveci*, was reported among 6% of patients in initial trials with combination cyclophosphamide and
corticosteroids and it is now the standard of care for patients to be prophylactically treated with double strength trimethoprim/sulfamethoxazole, three times weekly or atavoquone or dapsone for those intolerant of sulfa.

As in microscopic polyangiitis, plasma exchange may be useful in the context of severe or progressive renal failure or pulmonary hemorrhage, especially in the face of concomitant GBM positivity, and is the focus of an ongoing prospective trial.

In the case of symptomatic subglottic stenosis, optimal treatment of this is best achieved with localized treatment, with bronchoscopic mechanical dilatation, and transbronchial corticosteroid injection of the involved area [81].
DRUG-INDUCED VASCUITIS

Cases of vasculitis associated with the use of certain drugs, vaccines, and toxins have long been recognized. Previously these were described as hypersensitivity reactions causing small vessel vasculitis [82]. Cases ranging from self-limiting cutaneous involvement to severe multiorgan failure have been reported. Diagnosis is based simply on the development of vasculitis where a causal drug/agent can be identified, which in most cases leads to resolution of the vasculitis after drug discontinuation. There is great variation in the length of drug exposure before symptoms develop, with many reports of years of exposure before the apparent sudden onset of vasculitis.

The most commonly reported medications causing drug-induced vasculitis include propylthiouracil, allopurinol, hydralazine, cefaclor, minocycline, D-penicillamine, phenytoin, isotretinoin, and methotrexate with colony-stimulating factors [83]; quinolone antibiotics, and leukotriene inhibitors are more recently added to the list [84]. Other cases have been reported following vaccination, particularly hepatitis B [85] and influenza [86].

The pathophysiology of drug-induced vasculitis appears to be varied. Recently, cases of drug-induced vasculitis have been shown to be associated with temporary production of ANCA antibodies, typically against the MPO antigen and most notable with propylthiouracil and allopurinol [87]. Antibody titers also decrease in these cases following the discontinuation of medication, supporting a causal role [88].

Drug-induced vasculitis can involve medium or small vessels and therefore can present with a variety of clinical features depending on the site and size of vessel involved. Drug-induced vasculitis can present with clinical manifestations similar to any other systemic vasculitis, and there are no clinical findings specific to the syndrome. Skin involvement is common, most commonly in the form of palpable purpura. Although 33% of patients have no symptoms associated with the lesions, 40% complain of burning or pain. Bowel and nervous system involvement is also well recognized along with arthralgias and myalgias. Renal involvement is present in 40% of cases.

Treatment involves the withdrawal of potential causative medications. With mild skin involvement alone, no specific treatment is advocated. Where skin breakdown occurs, skin lesions are very symptomatic, or if internal organ involvement is identified, treatment with corticosteroids is beneficial. For rare cases, particularly those associated with ANCA production, other immunosuppressive agents may be necessary but usually only for short periods of time.
CNS VASCULITIS

CNS vasculitis is a rare condition that can present as a primary form confined to the CNS, known as primary angiitis of the CNS (PACNS) or as a secondary form associated with a systemic vasculitis or other systemic illness. Although many of the systemic vasculitides and rheumatologic diseases can result in CNS involvement and are discussed briefly in other sections, this section focuses on the CNS manifestations of PACNS. Other secondary causes of CNS vasculitis and syndromes mimicking CNS vasculitis include sarcoidosis; antiphospholipid antibody syndrome; lymphoma; atrial myxoma; atheroemboli; reversible vasoconstrictive syndrome; Lyme disease; HIV infection; herpes zoster; tuberculosis; and drugs including cocaine, methamphetamines, ergotamine, pseudoephedrine, and heroin [89].

The clinical presentation associated with PACNS is broad and includes subacute memory loss, acute encephalopathy, and other cognitive and behavioral changes. Seizures, cranial nerve abnormalities, focal deficits involving the cerebrum; cerebellum; and brainstem; spinal cord lesions; meninges; headache; auditory and vestibular disturbances; intracranial or subarachnoid hemorrhage; and reduced visual acuity or blindness due to retinal and optic nerve vasculitis have been described [90,91]. Frequently, patients have hypertension that aggravates their underlying disease or raises questions about their primary diagnosis. Disease manifestations may develop precipitously but often can present with a long prodrome over months involving subtle mental status changes and cognitive dysfunction [90,91]. The disease has a predilection for the small and medium vessels, especially of the leptomeninges and appears more common in men.

The diagnostic approach to CNS vasculitis includes a careful, frequently repeated neurologic examination; laboratory studies including cultures, viral and bacterial serologies, ANCA, cryoglobulins, antinuclear antibodies, antiphospholipid antibodies, and complement levels, which may help to establish secondary causes of CNS vasculitis related to infections, connective tissue disorders, and systemic vasculitides. CSF abnormalities seen in PACNS, including elevated protein levels and elevated cell counts, mostly lymphocytes, occurs in 80% of patients [91]. Angiographic changes showing alternating areas of stenosis and ectasia are suggestive of the disease but can be seen with other diagnoses.
including vasospasm and infection. In biopsy proven cases of PACNS, angiography is normal in 40% of cases [91,92]. Magnetic resonance imaging (MRI) can additionally be suggestive of ischemic lesions due to vasculitis if lesions are seen in different vascular distributions, although this finding is not specific for PACNS. A negative MRI and normal CSF make CNS vasculitis less likely, although cases of PACNS have been described with a negative MRI [93,94]. In most cases, unless angiography is highly suggestive in the correct clinical context, pathologic confirmation is necessary. Biopsy of the leptomeninges and other areas guided by previous imaging is necessary to rule out other diagnoses including infection, malignancy, and sarcoidosis, among other diagnoses. In PACNS, the inflammatory infiltrate is predominately mononuclear cells, but neutrophils, plasma cells, and histiocytes may also be noted [95].

Treatment of PACNS involves corticosteroids (CS) as the initial treatment of choice, ranging from doses of 1 mg/kg/d orally to 1 g intravenously daily for 3 days followed by oral CS. Cyclophosphamide is used for most cases or rituximab based on case reports although absolute recommendations are limited by a lack of prospective trials [96].

There are other vasculitic syndromes that can cause similar presentations, as discussed above, although they typically will present with CNS manifestations in the context of other systemic features such as fever, weight loss, peripheral neuropathy, glomerulonephritis, arthritis, or other organ involvement. PAN, GPA, and EGPA can all present with CNS involvement including seizure, cranial nerve deficit, cerebral vascular events, and subarachnoid hemorrhage [97–100].
OTHER VASCULITIDES

Takayasu’s arteritis is a large vessel vasculitis that affects the aortic arch and branches, affecting mainly women up to the age of 50. Patients typically present with constitutional symptoms of fatigue, weight loss, elevated erythrocyte sedimentation rate, and evidence of limb claudication and bruits. Patients can present with stroke due to inflammation and subsequent stenosis of the extracranial vessels [101]. Behcet’s disease is characterized by aphthous stomatitis, genital ulcers, and can sometimes present with vasculitis that can affect various-sized blood vessels. Meningoencephalitis, seizure, intracranial hemorrhage, and cerebral vascular events have been reported [102]. Connective tissue disease such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and Sjögren syndrome can all be associated with a variety of CNS manifestations including stroke, seizure, encephalopathy, and aseptic meningitis [101–105].
CHOLESTEROL EMBOLISM

Cholesterol crystal embolization can produce a clinical picture very similar to that of a systemic vasculitis [106,107] with the gradual onset of peripheral skin lesions, typically blue toe or livedo reticularis [108], with worsening renal function [109]. Bowel ischemia, acute confusional states [110], and retinal embolization may also be present.

The syndrome occurs due to the release of cholesterol crystals from eroded atherosclerotic plaques. It occurs most frequently following percutaneous endovascular interventions [111,112], but spontaneous episodes or those following anticoagulant [113] or thrombolytic therapy [114] have also been reported.

The chronology of impaired renal function after angiography may help distinguish radiocontrast dye-induced renal failure from renal failure due to atheromatous microemboli. Renal failure caused by radiocontrast dye tends to appear soon after the study, reaches maximal severity within 7 to 10 days, and then improves, with renal function returning to baseline over several weeks. In contrast, renal failure due to atheromatous microemboli to the kidney generally develops over 1 to 4 weeks or even over several months after the angiographic procedure and may not be reversible.

To establish the diagnosis of atheromatous emboli, one must have a high degree of suspicion based on the clinical presentation, history, physical findings, and laboratory results. The diagnosis is confirmed by the demonstration on histologic samples of biopsied skin, muscle, and kidney or amputated tissue of the characteristic biconvex needle-shaped clefts representing the “ghosts” of the cholesterol crystals within arteries and arterioles that are dissolved during routine histologic preparation [115]. With special histologic preparation, the cholesterol crystals display birefringence when viewed with a polarized light microscope.

Treatment of atheromatous emboli consists of controlling pain and blood pressure, and measures to increase local blood flow with topical glyceryl trinitrate (2% Nitrol) ointment, sympathetic blockade, calcium channel blockers to reduce vasospasm, and perhaps pentoxifylline to improve the rheostatic properties of red blood cells. Newer vasodilator agents such as iloprost and phosphodiesterase inhibitors are also being tried [116,117]. There are also case reports of improvements of cholesterol emboli-associated renal disease with statins [118]. Corticosteroid therapy has also been reported to be helpful in several case reports [119]. There are, however, no controlled trials of the use of any of these agents.

A number of modalities are ineffective for the treatment of atheromatous emboli, including the use of antiplatelet drugs and low-
molecular-weight dextran. The use of heparin and warfarin is controversial. The general consensus, however, is that these drugs are contraindicated, because by preventing the formation of an organized thrombus over ulcerated atheromatous plaques, anticoagulants may allow continued breakdown and embolization of material [120]. For cases of chronic distal embolization from abdominal aortic aneurysm, surgical repair or endovascular stent-graft repair usually leads to definitive resolution [121].
TREATMENT STRATEGIES IN UNDIFFERENTIATED RHEUMATIC DISEASES PRESENTING WITH CRITICAL ILLNESS AND RELAPSE OR WORSENING KNOWN RHEUMATIC DISEASE

Among certain circumstances, patients present to the hospital or ICU with overwhelming respiratory failure or hemodynamic instability without a previously defined rheumatic disorder. For example, patients with undiagnosed SLE or vasculitis may present with respiratory failure, alveolar hemorrhage, and rapidly progressive renal failure but no specific historical clues or previous serologic data supporting any particular diagnosis, and the results of laboratory and tissue evaluation biopsy may not yet be available. In this situation, one cannot be certain whether the underlying process is an immune complex–mediated disease, such as SLE, Goodpasture’s syndrome, or cryoglobulinemia, or a pauci-immune process such as GPA or microscopic polyangiitis. The appropriate laboratory evaluation would include an ANCA, ANA, antilglomerular basement membrane antibody, and cryoglobulins prior to initiating therapy. Initial therapy might include plasmapheresis, which may transiently remove autoantibodies, cytokines, and complement associated with the inflammatory process, in addition to high-dose methylprednisolone, 1 g intravenously per day for 3 days, and then initiation of intravenous or oral cyclophosphamide or rituximab [122,123]. The benefits of intravenous immunoglobulin for relapsing or life-threatening vasculitis are not well understood because of a paucity of controlled trials [124,125].

In the face of known rheumatic disease treatment failure, caution must be exercised to exclude infectious sources that may mimic worsening of the underlying disease process. Especially among patients taking chronic or high-dose corticosteroids and or cyclophosphamide, particular attention must be paid to exclude opportunistic infections such as P. jiroveci and fungal infections such as Aspergillus while deciding whether disease activity is escalating and becoming unresponsive to therapy. Once infection has been thoroughly excluded, one can consider either higher doses of a standard or novel immunosuppressive agent or addition of other therapies such as immunoglobulin or plasmapheresis.
Owing to the rarity of systemic vasculitis, there have previously been few prospective clinical trials evaluating accepted treatments. In recent years due to establishment of several investigator consortia, multicenter prospective studies are now beginning to be performed. The more important of these studies are summarized in Table 67.3.

The explosion of immunologic or genetically based therapies has affected all areas of medicine and, most dramatically, the fields of hematology/oncology, rheumatology, and transplantation medicine. Specific areas of dermatology, gastroenterology, neurology, nephrology, and allergy/immunology have also benefited from these therapeutics. Some of the following medications were initially FDA approved for a rheumatologic disease, then shortly thereafter approved for other indications. For example, adalimumab, a TNFα inhibitor initially approved for rheumatoid arthritis (RA), is also used for psoriasis, inflammatory bowel disease, and, most recently, uveitis. The reverse can also occur, and there is much crossover between different fields. Even therapies used for allergic asthma (such as omalizumab) are now also approved for idiopathic urticaria. To review all the immunologic and biologic medications of the various subspecialties is beyond the scope of this chapter. Some medications not discussed in this chapter are addressed in other sections such as hematology/oncology and pulmonary diseases, and in great detail in Chapter 63 on immunosuppression in solid organ transplantation.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

NSAIDs are very commonly used for rheumatologic diseases for their analgesic, anti-inflammatory, and antipyretic effects. There are numerous NSAIDs with variable dosing regimens available, but in the intensive care setting, comorbidities are common, thus limiting their use. NSAIDs are often contraindicated for critically ill patients because of their potential
toxicities (gastrointestinal bleeding, exacerbation of cardiac and renal dysfunction) and also have synergistic toxicities for those on anticoagulation.
CORTICOSTEROID THERAPY

Although NSAIDs are one of the first-line medications given for nonseptic inflammatory joint disease, corticosteroids are commonly given for many rheumatologic and dermatologic diseases for their potent anti-inflammatory effects. However, the physiology and mechanism of action of corticosteroids are beyond the scope of this chapter.

The body typically produces 5.7 mg/m²/d of cortisol [1]. Exogenous corticosteroids at a dose equivalent of prednisone 5.0 to 7.5 mg per day inhibit the hypothalamic–pituitary–adrenal axis. Guidelines are controversial and suggest that supplementation beyond a patient’s baseline dose in times of stress can be deferred for those receiving <5 mg of prednisone or its equivalent daily and for those on alternate-day dosing. However, those on corticosteroids chronically (greater than 3 weeks) at >10 mg daily or those who have clinical Cushing syndrome require stress doses during situations such as surgery, sepsis, trauma, or serious medical illness. This is especially relevant for patients with systemic rheumatologic disorders with major organ involvement (i.e., newly diagnosed myositis, lupus, vasculitis) because extended courses of medium- to high-dose steroids are the therapeutic mainstay of treatment for these diseases.

Several corticosteroid preparations are available, which differ in potency, half-life, and mineralocorticoid activity. In the ICU, the most commonly used corticosteroids are hydrocortisone, methylprednisolone, and prednisone. Glucocorticoids can be affected by age, severe liver disease, hyperthyroidism, hypoalbuminemia, hemodialysis, and certain medications such as anticonvulsants, erythromycin, or ketoconazole.

The dosage and mode of administration of corticosteroids depend on the clinical situation. As mentioned earlier, rheumatologic diseases with major organ involvement require high doses—typically around 1 to 1.5 mg/kg/d—to achieve disease control. However, for acutely ill patients, high-dose steroids usually with pulse IV methylprednisolone at 1,000 mg daily for 3 consecutive days will often be given prior to initiating a regimen of 1 to 1.5 mg/kg/d. Pulse IV methylprednisolone may produce minor side effects (metallic taste, facial flushing, transient hypertension, and hyperglycemia), but significant (although rare) toxicities such as seizures, psychosis, intractable hiccups, arrhythmias, hemiplegia, and sudden death (more typically from arrhythmias or cardiovascular collapse) can occur. Other toxicities with longer-term use include peptic ulcer disease, fluid retention, dyslipidemia, increased risk for infection, osteonecrosis, and osteoporosis. Tapering regimens vary depending on the disease and dose of steroid.
DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDs)

DMARDs were initially used for rheumatic diseases as steroid-sparing agents. However, convincing evidence exists that these agents can produce dramatic improvement or induce remission in many different rheumatic diseases. The most commonly used drugs include hydroxychloroquine, sulfasalazine, methotrexate, azathioprine, mycophenolate mofetil, leflunomide, and cyclophosphamide. Cyclosporine and gold are older medications that have fallen out of favor for the treatment of rheumatologic disease as newer agents with less toxicity have emerged. Calcineurin inhibitors have also been used less commonly in rheumatoid arthritis and lupus nephritis as steroid sparing agents. However, these medications are not addressed here. See chapter 63 for more detailed discussion.

DMARDs all typically have immunosuppressive effects except for perhaps hydroxychloroquine, a medication previously used to prevent malaria. In an ICU setting, patients are severely ill perhaps with active infection, sepsis, cytopenias, major organ failure, and/or issues requiring surgery. In all of these cases, cytotoxic therapy is typically held until the acute issues are resolved. If the rheumatologic disease becomes active while the DMARD is held, glucocorticoids can be given in the lowest minimal dose necessary, assuming there is no contraindication. Adjustments to conventional dosing may be necessary depending on renal or hepatic function. Further details for the most common DMARDs will be discussed in the following section.

Mechanism of Action and Metabolism

**Hydroxychloroquine** works by elevating the pH within intracellular vacuoles, thus altering the environment required for antigenic protein digestion and the molecular assembly of peptide complexes, namely, the formation of peptide–MHC protein complexes. These complexes are required to stimulate CD4+ T cells, so when the complexes are not allowed to form, there is downregulation of the immune response against autoantigenic peptides. The major toxicity is retinal toxicity typically after 7 years, gastrointestinal issues, rash, and myopathy.

The other immunosuppressive agents interfere with the cell cycle, and cytotoxic effects occur through inhibition of cell division.

**Sulfasalazine** is a combination of sulfapyridine and 5-aminosalicylic acid linked by a diazo bond. Sulfasalazine alters neutrophil function,
inhibits the cytotoxicity of the natural killer cells, and decreases levels of IL-1, TNF-α, and IL-6. Sulfasalazine also inhibits matrix metalloproteinase activity and matrix remodeling.

**Methotrexate (MTX)** inhibits dihydrofolate reductase, thus reducing intracellular tetrahydrofolate levels and interfering with tetrahydrofolate-dependent metabolic pathways, which include purine and pyrimidine metabolism. Potential mechanisms whereby MTX exerts an anti-inflammatory effect include increased extracellular adenosine concentrations, reduction of proinflammatory cytokines (IL-1β and IL-6), inhibition of cyclooxygenase and lipoxygenase activity, and induction of apoptosis. MTX and its metabolites are excreted by the kidney and so should not be used for patients whose estimated glomerular filtration rate is less than 30 mL per minute.

**Azathioprine (AZA)**, a purine analog, prevents the biosynthesis of purine bases. AZA is a prodrug that is metabolized in the liver to 6-mercaptopurine and then, through the enzyme thiopurine S-methyltransferase (TMPT), to its active metabolites. A genetic polymorphism of TMPT results in variable enzyme activity and predicts greater risk of myelosuppression for patients at low or undetectable levels. TMPT genotype testing is recommended before initiating AZA therapy [2]. Because 45% of the prodrug is renally excreted, the dose should be reduced for patients with renal insufficiency, but specific recommendations are not available. AZA should be avoided, or the dose markedly reduced, in patients taking allopurinol, which interferes with its metabolism by inhibiting xanthine oxidase. However there are exceptions to this rule and the combination of AZA and allopurinol is sometimes used in treating inflammatory bowel disease and autoimmune hepatitis to optimize thiopurine therapy.

**Mycophenolate mofetil (MMF)** is a reversible inhibitor of inosine monophosphate dehydrogenase, resulting in reduced purine synthesis and consequent inhibition of T- and B-cell proliferation. The antiproliferative effects of MMF are relatively specific for lymphocytes. Other potential mechanisms of MMF-induced immunosuppression include the induction of T lymphocyte apoptosis and inhibition of adhesion molecule expression. Most of the MMF dose (90%) is excreted renally and the remainder by enterohepatic elimination. Dose adjustment is necessary in patients with renal insufficiency.

**Leflunomide (LEF)** selectively inhibits dihydroorotate dehydrogenase, an enzyme critical in the de novo synthesis of pyrimidine ribonucleosides. By reducing the pyrimidine pool and thus inhibiting DNA synthesis, LEF is postulated to modulate pathogenic T-cell proliferation and the subsequent inflammatory cascade. LEF has a very long half-life, is highly protein bound, undergoes enterohepatic recirculation, and is eliminated by the gastrointestinal tract and by
excretion in the urine. It should not be used for patients with hepatic impairment.

**Cyclophosphamide (CY)** is an alkylating agent that can be given by mouth or intravenously. It binds to DNA and prevents cell replication. CY is cytotoxic to both resting and dividing lymphocytes. It globally reduces T-cell function, and reduces B-cell numbers and antibody production. CY is metabolized by the liver to several active and inactive compounds that are also excreted in the urine. Dose adjustment is recommended for patients with renal insufficiency (Table 68.1). Hepatic impairment does not appear to alter CY clearance, although both hepatic and renal function should be monitored.

**TABLE 68.1 Intravenous Cyclophosphamide Therapy (IVCY)**

1. Initiate IV hydration at 200–500 mL/h
   Normal or ½ NS for 1 L over 1–2 h if CrCl >50 mL/min and depending on cardiac status. (If medical status prevents adequate hydration, MESNA can be substituted—see below.)

2. Antiemetic treatment
   Ondansetron, 8 mg IV 30 min (or PO 60 min), prior to CY and then 8 mg every 8 h for 24 h

3. MESNA (for CrCl <50 mL/min or inadequate prehydration due to cardiopulmonary status)
   Give 100% of total CY dose in divided doses: Infuse each dose over 15 min. Give 20% of CY dose (mixed in 50 mL of D5 W) 30 min prior to CY, then 40% of CY dose at 4 and 8 h following CY.

4. Cyclophosphamide: Initial dose is 500–750 mg/m² in 250 mL NS over 60 min. Subsequent dose is based on WBC nadir obtained 10-14 days after infusion after infusion.
   Dose adjustments
   a. CrCl 10–50 mL/min: 75% of CY dose
   b. CrCl <10 mL/min: 50% of CY dose
c. Hemodialysis patients: 50% of CY dose after dialysis
d. Subsequent month dose: increase or decrease by 10%–20% of previous dose based on WBC nadir.

5. Posthydration fluid is identical to prehydration. Monitor adequate urine output and encourage frequent voiding for 24 h after IVCY. In patients without indwelling Foley catheter, avoid CY infusion after 4 PM to reduce prolonged bladder contact with CY metabolites overnight.

---

CY, cyclophosphamide; D5W, dextrose 5% in water; IV, intravenous; MESNA, sodium 2-mercaptoethane sulfonate; NS, normal saline; PO, by mouth; WBC, white blood cells.

CY is typically used for organ-threatening manifestations of rheumatologic diseases, primarily for lupus and vasculitis. There are different dosing regimens, depending on the disease and the manifestations. We have provided one of the more typical dosing regimens in Table 68.1. In the rare event that CY has to be given to a critically ill patient, caregivers would need to ensure that there is adequate urinary drainage by catheter to protect the bladder from CY-associated hemorrhage from stasis; an hourly urine flow of 100 mL per hour is recommended. Sometimes, continuous bladder irrigation through a three-way catheter may be needed if patients have a lower urine output.

Certain medications can also affect the hepatic microsomal enzymes, thus altering the metabolism of CY. Those that induce these enzymes (i.e., barbiturates, phenytoin, and rifampin) can potentially increase toxicity, whereas those that inhibit the hepatic microsomal enzymes (allopurinol, antimalarials, corticosteroids, tricyclic antidepressants) can decrease efficacy. Another medication interaction that can have important consequences is succinylcholine. Anesthesiologists need to be aware that both succinylcholine and CY inhibit plasma pseudocholinesterase activity, thereby leading to the potential for prolonged neuromuscular blockade if given concomitantly.
Toxicities

Toxicities common to all of the foregoing immunosuppressive agents include bone marrow suppression, infections, and gastrointestinal irritation. Bone marrow toxicity may occur at any time. Infections secondary to immunosuppression occur with any drug but do not necessarily correlate with the degree of leukopenia, duration of drug therapy, or concomitant corticosteroid therapy. Prior to starting these medications patients should be screened for hepatitis B and C because these immunosuppressants can reactivate infection in hepatitis B carriers or worsen preexisting disease. In addition, MMF has also been associated with progressive multifocal leukoencephalopathy (PML) which can be fatal.

MTX has similar adverse effects, which include cytopenias, hepatotoxicity, alopecia, and skin photosensitivity, as well as more minor toxicities, which include nausea, vomiting, anorexia, diarrhea, weight loss, and stomatitis. MTX can also be associated with pulmonary toxicities too, most commonly hypersensitivity pneumonitis, which usually improves with discontinuation of methotrexate, supportive care, and glucocorticoids if needed. Other pulmonary toxicities include interstitial fibrosis, pleuritis, noncardiogenic pulmonary edema, and increased pulmonary nodulosis.

Small series have also reported development of lymphoproliferative disorders in MTX-treated patients. However, RA patients are already at greater risk for lymphoma than the general population. A study reviewing a national data bank for rheumatic disease in over 18,000 patients did not identify a significantly higher risk of lymphoma for patients treated with MTX [3]. Risk factors for MTX toxicity include renal insufficiency, viral infections, folic acid deficiency, and concurrent use of trimethoprim-sulfamethoxazole and probenecid. For MTX overdose, folinic acid (leucovorin), in a dose equal to the MTX dose, should be given every 4 to 6 hours until the serum MTX level is no longer detectable.

Toxicities associated with LEF include diarrhea, alopecia, rash, hypertension, weight loss, hepatotoxicity, and anemia. Hepatotoxicity can be significant, and there have been reports of hepatic failure and death. The extended half-life of LEF can be problematic, especially for patients who experience severe side effects or who wish to become pregnant. For these cases, elimination of LEF and its metabolites can be accelerated by the administration of cholestyramine, 8 g three times a day for 11 days.

Specific toxicities of AZA include pancreatitis and hypersensitivity hepatitis with transaminitis and cholestasis that usually resolve after drug discontinuation, although irreversible damage has been reported. Azoospermia, anovulation, and teratogenesis are unusual. TPMT levels do not predict these toxicities, in contrast to the known association of low
enzyme levels with risk of myelosuppression. It is uncertain whether neoplasia occurs at a greater incidence among rheumatic patients treated with AZA as compared to transplantation patients. However, relative risk of lymphoproliferative disorders among RA patients receiving AZA is estimated at 2.2% to 8.7%.

The toxicity profile of MMF is similar to AZA and includes hepatoxicity and cytopenias. Hepatic fibrosis is an infrequent but concerning complication. Gastrointestinal intolerance with nausea, vomiting, and diarrhea may improve over time and seldom requires drug discontinuation. Rarely, an enterocolitis has been associated with MMF. A delayed release formulation (mycophenolic acid) is available that may improve gastrointestinal tolerance. As with other immunosuppressive medications, there may be an increased risk of malignancies, including lymphoma.

Similar to the other DMARDs, CY can also cause bone marrow suppression. However, CY can have further major side effects, including infertility, bladder toxicities, and carcinogenicity. Oral and IV regimens can induce gonadal dysfunction in men and women because of injury to germinal epithelium. Azoospermia in males and amenorrhea in premenopausal women is dose related and is usually permanent. The risk may be reduced by the induction of gonadal quiescence during CY treatment, such as using leuprolide to preserve ovarian function in women with lupus nephritis treated with CY [4]. Leuprolide was ineffective for men, but a small study has shown a reduced risk of azoospermia in men treated with testosterone [5]. Sperm banking is also recommended for men undergoing CY therapy. Cryopreservation of ova or embryos can be recommended but is sometimes impractical because it entails hormonal manipulation and significant delay in treatment.

Hemorrhagic cystitis due to acrolein, a metabolite of CY, occurs in 20% to 30% of patients receiving oral CY. Bladder carcinoma occurs in 10% of patients who receive long-term CY therapy, even 20 years after exposure. IV CY may have fewer bladder complications than the oral regimen. Adequate hydration for all patients and concomitant use of sodium 2-mercaptopoethane sulfonate (MESNA) during IV CY infusion for patients with renal insufficiency should be used to reduce the risk of hemorrhagic cystitis. The regimen is outlined in Table 68.1. Skin and hematologic malignancies and premalignant and malignant changes of the cervix are also associated with CY. Hepatotoxicity is rare, but nausea or vomiting with IV CY is common. Other toxicities include infections, cardiomyopathy, and pulmonary fibrosis. PJP has also occurred in patients with autoimmune diseases treated with CY and steroids. PJP prophylaxis is recommended for all patients treated with CY.
BIOLOGIC MODIFIERS

In addition to the foregoing traditional immunosuppressive agents, there has been continued growth in the development of biologic modifiers for the treatment of rheumatic diseases. The mechanisms of action vary and include anticytokine therapies, T-cell costimulation blockade, B-cell depletion and inhibition, phosphodiesterase 4 (PDE4) inhibition, and Janus kinase (JAK) enzyme blockade (see Table 68.2.). Biologic agents are increasingly used to treat RA, psoriatic arthritis (PsA), ankylosing spondylitis, inflammatory bowel disease, and even lupus. It is unlikely that the ICU physician will initiate any of these agents for therapeutic indications. However, if a patient is receiving one of these agents chronically, it is important for the ICU team to understand the mechanism of action and the potential complications or toxicities of these therapies [6].

### Treatments for RA

Treatments for RA are diverse and include six TNF-α inhibitors, one IL-6 inhibitor, one JAK inhibitor, and agents that work through T-cell costimulation blockade and B-cell depletion. There are also two IL-1 antagonists, although these are used less commonly.

The TNF-α inhibitors are also used to treat spondyloarthropathies, such as psoriatic arthritis and ankylosing spondylitis. However, newer agents have emerged that work through PDE4 inhibition and the inhibition of cytokines IL-12, IL-23, and IL17A. A brief summary of mechanism of action and toxicity for each of these agents follows.

### TNF-α Inhibitors

p. 628
treatment of moderate to severe RA, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease. Although TNF-α has many diverse cellular effects for RA and other inflammatory arthropathies, it acts as a potent inflammatory cytokine by binding to one of its receptors, p55 or p75, on chondrocytes, fibroblasts, and osteoclasts in the rheumatoid synovium. This binding stimulates the production of metalloproteinases and other effector molecules that damage the joint. In addition, TNF-α–activated endothelial cells express adhesion molecules, which promote the ingress of polymorphonuclear (PMN) cells into the joint. Naturally occurring soluble TNF-α receptors, which theoretically should neutralize TNF-α, exist in high concentrations in rheumatoid synovial fluid but may be inadequate in concentration to neutralize TNF-α in this disease.

Infliximab, a chimeric (human and mouse) monoclonal antibody against TNF-α, is administered intravenously at doses that can be titrated up from 3 to a maximum of 10 mg per kg every 4 weeks to 8 weeks depending on the severity of a patient’s disease. On April 5, 2016, the FDA approved a biosimilar to infliximab also given by IV infusion. A biosimilar is a product that is essentially “interchangeable” or “highly similar” to the reference product in terms of mechanism of action, dosage and strength, and route of administration. In addition, the biosimilar product must not have any clinically meaningful differences in efficacy or safety profile compared to the reference drug.

Etanercept, a fusion protein comprising two recombinant p75-soluble TNF-α receptors combined with the Fc portion of human IgG, is administered by SQ injection (25 mg twice a week or 50 mg weekly). Adalimumab and golimumab are recombinant human IgG1 monoclonal antibodies against TNF-α administered as a 40 mg SQ injection every other week, and 50 mg SQ injection every month, respectively. In August of 2016, the FDA approved etanercept-sz.zs, a biosimilar to etanercept and in September of 2016, adalimumab -atto, a biosimilar to adalimumab, was approved.

Certolizumab is a pegylated human anti-TNF-α antibody Fab’ that is given SQ every 2 to 4 weeks. MTX is recommended in combination with infliximab and adalimumab to reduce the frequency of neutralizing human/antichimeric antibodies or human/antihuman antibodies, respectively. However, the role of MTX use with golimumab and certolizumab to prevent these sorts of antibodies is not as clear. Studies have previously shown that the combination of methotrexate with these biologics works better than either one alone, but the self-injections are now often used as monotherapy.

Short-term toxicities of etanercept, adalimumab, golimumab, and certolizumab include injection site reactions with local urticarial lesions that often resolve with subsequent repeated dosing. Mild hypersensitivity
reactions with infliximab infusions occur in 20% of patients, but 2% will experience severe infusion reactions. There is an increased risk of serious infections among patients taking all TNF-α inhibitors, including opportunistic, fungal, and mycobacterial infections. All patients should be tested for latent TB before initiating therapy with a TNF-α inhibitor, and patients with known hepatitis B infection should not receive these drugs.

Demyelinating syndromes have been reported in patients treated with TNF-α inhibitors. Immunogenicity, low-titer anti-dsDNA antibody, and drug-induced lupus syndromes have been documented in patients treated with TNF-α inhibitors. Pancytopenia, aplastic anemia, elevated liver function tests, and exacerbation of preexisting or new onset congestive heart failure have all been reported. Long-term toxicities, including an increased risk for malignancy, are ongoing concerns, although the data are inconclusive. Initial surveillance suggested a higher incidence of lymphoma and nonmelanoma skin cancers. However, a Cochrane review looking at the adverse effect of biologics (including not only TNF-α inhibitors but also abatacept, tocilizumab, rituximab, and anakinra) revealed that there was no statistically significant difference in the rate of lymphoma compared to controls [7]. Other studies from large patient data registries from the United States [8] and Europe [9] have also not shown increased malignancy rates associated with TNF-α inhibitors.

**IL-1 Inhibitors**

IL-1, produced by rheumatoid synovial macrophages, acts synergistically with TNF-α on synovial fibroblasts, chondrocytes, endothelial cells, and osteoclasts. These interactions promote the influx of PMN cells into the joint, release of metalloproteinases and collagenases from chondrocytes, and activation of osteoclastic bone resorption. IL-1 binds to two types of cell-surface receptors, but only type I is capable of intracellular activation. IL-1 inhibition has had modest benefit for RA but has been found to be effective primarily in a group of rare, inherited, autoinflammatory diseases called the cryopyrin-associated periodic syndromes (CAPS).

There are three medications that inhibit IL-1—anakinra, canakinumab, and rilonacept. Anakinra is a recombinant IL-1 receptor antagonist, which blocks the biologic activity of both IL-1α and IL-1β by competitively inhibiting IL-1 binding to the IL-1 type 1 receptor. Anakinra is given once daily and approved for the treatment of moderate to severe RA and CAPS. Canakinumab is a human monoclonal IL-1β antibody, which targets interleukin-1 β (IL-1β), thereby blocking its interaction with IL-1 receptors and neutralizing IL-1β activity. Canakinumab is given once a month and is approved for CAPS and systemic juvenile idiopathic
arthritides (SJIA). Rilonacept prevents both IL-1α and IL-1β from binding to the IL-1 receptor complex on the surface of effector cells that mediate the proinflammatory response. It is given once weekly and is only approved to treat CAPS. Toxicities for all of the IL-1 inhibitors include injection site reactions, especially with anakinra, immunosuppression, leading to an increase of serious infections, cytopenias, and hepatotoxicity.

**IL-6 Inhibition**

IL-6, a proinflammatory cytokine expressed in RA synovial tissues, promotes the activation of B-cells, T cells, and macrophages, and upregulation of endothelial adhesion molecule expression. IL-6 also stimulates osteoclast maturation and promotes bone erosion. There are two FDA approved medications inhibiting IL-6 in rheumatoid arthritis, tocilizumab and sarilumab, the latter just approved May 2017. Tocilizumab, a humanized IgG1 anti-IL-6 receptor antibody, is approved for the treatment of RA, polyarticular JIA, SJIA, and giant cell arteritis. Sarilumab is similar and also a human recombinant monoclonal antibody that binds soluble and membrane-bound IL-6 receptors (sIL-6R and mIL-6R), thus inhibiting IL-6-mediated-signaling. Sarilumab is only approved for adult RA. Typically, both are used for patients who fail to respond to DMARDs and TNF-α inhibitors. Tocilizumab can be administered as a monthly IV infusion or as an injection every 1 to 2 weeks (depending on weight and severity of disease) either alone or in combination with weekly methotrexate. Sarilumab is given as a subcutaneous injection in 2 doses—150mg or 200mg every 2 weeks. The risk of serious infection is similar to that of TNF-α inhibitors. TB has been reported, but there are insufficient data to quantify the risk. To date, there is no evidence of an increased incidence of malignancies among RA patients treated with tocilizumab. In clinical trials, tocilizumab has also been associated with hypertension, hypercholesterolemia, elevated liver transaminases, and intestinal perforation.

**IL-12 and IL23 Inhibition**

Ustekinumab is a human monoclonal antibody directed against the p40 subunit common to IL-12 and IL-23. Ustekinumab was initially studied for psoriasis because concentrations of IL-12 and IL-23 are higher in psoriatic lesions. In addition, cytokines induced by IL-12 (IFN-γ) and IL-23 (IL-17A, IL-17F, and IL-22) are also elevated in psoriatic plaques [10].
Further studies demonstrated that ustekinumab also benefits PsA and has now been approved to treat both psoriasis and PsA. It is initially given by subcutaneous injection at weeks 0 and 4, and then every 12 weeks. Phase 2 trials of ustekinumab for RA and ankylosing spondylitis are ongoing. Adverse events are similar to the other biologic agents and include injection site reactions; increased risk for atypical infections, including reactivation of tuberculosis; increased risk for nonmelanoma skin cancers; reversible posterior leukoencephalopathy syndrome (rare); and hypersensitivity reactions. There also appears to be a risk for antibody formation to ustekinumab.

**IL-17A Inhibition**

Secukinumab is a high-affinity human immunoglobulin G1 monoclonal antibody that selectively binds to and neutralizes IL-17A. Cells that produce IL-17A are increased in the circulation, joints, and skin plaques in patients with PsA [11,12]. In addition, levels of IL-17+CD8+ T cells have been shown to correlate with disease activity measures and erosions/structural joint damage [11]. Secukinumab was approved for the treatment of moderate to severe plaque psoriasis in January of 2015, and then soon after for the treatment of ankylosing spondylitis and psoriatic arthritis in January of 2016. Adverse reactions include more frequent infections such as nasopharyngitis and upper respiratory tract infections. Four strokes and two myocardial infarctions were also reported in the secukinumab groups versus zero in the placebo group, so more studies need to be done [13].

**B-Cell Depletion**

Rituximab (RTX), a chimeric monoclonal antibody to CD20 that results in the depletion of mature B-cells and disruption of T-cell activation, is now approved for three rheumatologic conditions—moderate to severe RA in a patient who has failed other DMARDS and a TNF inhibitor; granulomatosis with polyangiitis (previously known as Wegener’s granulomatosis); and microscopic polyangiitis. Rituximab is usually given with methotrexate when used for RA. For the vasculitides, rituximab is typically given with glucocorticoids as they are being tapered. Toxicities include infusion reactions with hypotension, fever, and nausea. Serious and potentially fatal viral infections include reactivation of hepatitis B with fulminant hepatitis and hepatic failure. In terms of infection risk, respiratory tract infections appear to be the most common with rituximab. In addition, a link has been found between those with preexisting hypogammaglobulinemia and increased risk of further reduction of immunoglobulin G (IgG) levels thus leading to
serious infections after rituximab therapy \[14\]. Rates of opportunistic infections or tuberculosis do not appear to be increased, and no increased risks for malignancies have been reported in the limited follow-up of treated RA patients. Data from the non-Hodgkins lymphoma database as well as a national registry looking primarily at the use of rituximab for autoimmune diseases have been reassuring, in that serious adverse events were infrequent \[15\]. However, there are case reports of progressive multifocal leukoencephalopathy (PML) in patients with RA and systemic lupus erythematosus (SLE) that has led to death.

**B-Lymphocyte Stimulator Inhibition**

Belimumab is a human IgG1λ monoclonal antibody that effectively targets the soluble form of B-lymphocyte stimulator (BlyS), which in turn inhibits the development and homeostasis of B lymphocytes \[16\]. This inhibition is thought to block autoantibody production responsible for the clinical features of lupus \[16\]. Belimumab was approved by the Food and Drug Administration in 2011 for the treatment of active SLE for patients currently receiving standard therapy (e.g., glucocorticoids, antimalarials, immunosuppressants, and NSAIDs). Standard dosing is 10 mg per kg given intravenously on days 0, 14, and 28, and then every 28 days thereafter. Data obtained after 52 weeks from Phase III trials (BLISS-76 and BLISS-52) noted belimumab improved overall SLE disease activity in the most common musculoskeletal and mucocutaneous organ domains \[17\]. Subjects with severe active lupus nephritis or central nervous system involvement were excluded from these trials, but patients with baseline proteinuria >0.2 g per 24 hours had significantly greater median percent reductions in proteinuria during weeks 12 to 52 than those treated with placebo \[18\]. Belimumab has been well tolerated with a safety profile that is comparable to placebo in terms of rates of infections and malignancies.

**T-Cell Costimulation Blockade**

Abatacept, a selective modulator of T-cell activation, is approved for the treatment of moderate to severe RA for patients who have an inadequate response to methotrexate, other DMARDs, or TNF-α inhibitors. Abatacept can be given intravenously or by SQ injection once a week. T-cell activation requires two signals. The first is generated by the binding of a T-cell receptor (TCR) to an antigen presented by a major histocompatibility complex (MHC) on an antigen-presenting cell. The second, costimulatory signal is generated through a connection between CD80/86 on APCs and the CD28 receptor on T cells. To balance out T-cell activity, another protein receptor on the surface of T cells, cytotoxic
T-lymphocyte-associated protein 4 (CTLA4), downregulates T-cell activation. Abatacept is a soluble fusion protein comprising the extracellular domain of CTLA4 and the Fc portion of IgG1 (CTLA4-Ig) that interferes with T-cell activation by binding to CD80/86, thereby inhibiting the required costimulatory signal. Toxicities include hypersensitivity infusion reactions, infections, exacerbations of chronic obstructive pulmonary disease (COPD), and potential concerns about malignancies, including lymphoma and lung cancer though as mentioned earlier, data is not clear.
Tofacitinib was approved by the FDA on November 2012 for RA and was the first orally administered Janus kinase (JAK) inhibitor [19]. Tofacitinib works by entering immune cells and binding to the adenosine triphosphate (ATP) binding cleft of JAK1 and JAK3. This binding inhibits the autophosphorylation and phosphorylation of tyrosine residues, thereby preventing the activation of signal transducer and activator of transcription (STAT) molecules. When STAT molecules are not activated, gene transcription and cytokine production are inhibited, leading to decreased synovial inflammation and structural joint damage in RA patients. Toxicities include cytopenias, dyslipidemia, elevations in creatinine and transaminases, and immunosuppressive effects, including reactivation of latent tuberculosis. Malignancy risk (excluding nonmelanoma skin cancers) was within the expected range for patients with moderate to severe RA [20].

Phosphodiesterase 4 (PDE4) Inhibition

Apremilast is a small molecule inhibitor of PDE4 that was approved for the treatment of moderate to severe plaque psoriasis and psoriatic arthritis. Apremilast is an oral drug that inhibits PDE4, thereby blocking the degradation of cyclic adenosine monophosphate (cAMP). As a result, elevated levels of cAMP downregulate proinflammatory cytokines such as IL-12, IL-23, TNF-α, and IFN-γ, thus decreasing inflammation. Benefit to the skin is more modest, although PDE4 is expressed in cell types present in the joints and skin [21]. The most common adverse events are gastrointestinal (typically diarrhea and nausea), and they usually occur early and are self-limiting. Serious reactions include depression, suicidal ideation, and hypersensitivity. There has been no significant increase in major adverse cardiac events, serious or opportunistic infections, malignancies, or laboratory abnormalities compared to placebo [22]. The favorable infection profile and decreased need for regular lab monitoring make this drug desirable.
INTRAVENOUS IMMUNOGLOBULIN (IVIG)

Immunoglobulin therapy is a blood product made of pooled polyvalent IgG antibodies extracted from the serum of a large number of donors. It is the mainstay therapy for patients with hereditary or acquired immunodeficiency. In addition, IVIG has been used to treat several immune-mediated diseases. There is good supporting evidence for use against Kawasaki disease, immune thrombocytopenia purpura, chronic, demyelinating polyneuropathy (CIDP), and Guillaine Barre syndrome [23]. IVIG is also used as second-line therapy for dermatomyositis and polymyositis, and in some cases of ANCA-associated vasculitides [23]. The mechanism of action is thought to be complex and not completely understood. IVIG has been used in antiphospholipid antibody syndrome and CAPS, but the evidence does not support its use in CAPS unless complicated by significant autoimmune thrombocytopenia [23].

The dosing of IVIG varies depending on the disease being treated. For immunodeficiency states, dosing is usually 300 to 800 mg per kg every 3 to 4 weeks. In contrast, a typical regimen may be 2 g per kg over 5 days for CIDP or polymyositis. IVIG is generally considered safe therapy, but immediate side effects can include malaise, fatigue, headache, arthralgias, myalgias, flushing, chest tightness, fever, chills, gastrointestinal upset, changes in blood pressure, and anaphylactic reactions [24]. Late adverse reactions are quite rare but can include thromboembolic events in up to 2% of patients [24]. Slowing down the infusion rate and giving a lower concentration of IVIG can decrease this risk.
DMARDs, BIOLOGICS, AND PREGNANCY

Most DMARDs are also teratogens and contraindicated in pregnancy, although hydroxychloroquine, sulfasalazine, AZA, and sometimes cyclosporine are tolerated in those with severe disease. MTX and LEF are rated as pregnancy class X (contraindicated, risk outweighs benefits), and should not be used during pregnancy. AZA, although rated as class D (positive evidence of risk), is considered safer than many other immunosuppressive agents during pregnancy, based on the literature in the transplantation population. When the benefit of immunosuppression appears to outweigh the risks (e.g., in renal transplant recipients, active lupus, or inflammatory bowel disease), AZA is preferred over other immunosuppressive medications. We strongly recommend avoidance of CY and MMF (both pregnancy class D) during pregnancy except for life-threatening medical conditions in which no alternative therapy is available.

Data on the safety of biologic agents are limited primarily to case reports largely looking at TNF-α inhibitors. However, collective evidence suggests that exposure to TNF-α inhibitors at conception or during the first trimester does not result in an increased risk of adverse pregnancy and fetal outcomes [25]. There is much less data about other biologic therapies. As of the time of this publication, the TNF-α inhibitors, ustekinumab, and anakinra are rated pregnancy class B (no evidence of risk). Abatacept, rituximab, belimumab, tocilizumab, tofacitinib, and apremilast are all class C (risk cannot be ruled out). Use of these biologic agents should be avoided during pregnancy unless no alternative therapies are available.
SUMMARY

A critically ill patient who has recently received one of the above DMARDs or biologic agents should be approached as an immunocompromised host. Most are immunosuppressive except for perhaps hydroxychloroquine and apremilast. Atypical or opportunistic infections are high on the differential if the patient is febrile. In addition, other toxicities of these drugs can include cytopenias, liver function abnormalities, atypical neurologic symptoms, and congestive heart failure. Given the critical nature of the illness that requires ICU care, it is prudent to postpone patients’ scheduled doses of these DMARDs or biologic agents until their medical status is more stable.
REFERENCES

Anaphylaxis is the most severe and potentially fatal form of the immediate hypersensitivity reactions. The term *anaphylaxis* (antiphylaxis) is derived from Greek and means “against protection” [1]. It describes the shock-like state that is caused by contact with a substance and contrasts with the term *prophylaxis*, which denotes a beneficial or protective state resulting from contact with a substance.

The clinical features of anaphylactic reactions are the physiologic sequelae of release of chemical mediators from tissue-based mast cells and circulating basophils and include a potential for life-threatening vascular collapse and respiratory obstruction [2,3]. A clinically and physiologically indistinguishable hypersensitivity reaction, which is called an anaphylactoid reaction, differs from anaphylactic reactions only because the chemical mediators are released by nonimmunologic mechanisms. Since the clinical features are indistinguishable, both will be referred to collectively as anaphylactic reactions [4].

Estimation of the annual incidence of anaphylactic reactions from administrative sources is hampered by complex coding and incomplete reporting. Anaphylaxis is frequent, with approximately 50 to 103 cases occurring per 100,000 person-years [5]. The case fatality rate from anaphylaxis is estimated at 0.25% to 0.33% of hospitalizations and emergency department visits for anaphylaxis [6]. In a separate study, examination of a United States database identified 2,458 deaths from anaphylaxis from 1999 to 2010 [7].

**PATHOPHYSIOLOGY OF ANAPHYLACTIC REACTIONS**
Mechanisms of Release of Chemical Mediators

For humans, anaphylaxis involves a series of steps that result in the release of chemical mediators from tissue-based mast cells and circulating basophils. First, contact with an antigen stimulates the generation of antibodies of the immunoglobulin E (IgE) class. Next, the IgE molecules bind by way of their Fc receptor to a glycoprotein receptor on the cell-surface membrane of tissue mast cells and blood-borne basophils, the so-called target cells. As many as 4,000 to 100,000 IgE molecules normally bind to a single target cell, and up to 100,000 to 500,000 among atopic individuals [7,8]. This binding may remain for weeks to months. When two IgE molecules with the same Fab-binding (antigen-recognition) specificity are in close proximity on the surface of mast cells and basophils, the cells are termed sensitized.

For subsequent antigenic exposure to stimulate the release of mediators from mast cells and basophils, the specific antigen must bind to the Fab portion of two IgE molecules fixed to the surface of the target cell. This bridging of two IgE molecules initiates a series of biochemical modifications called the activation–secretion response (Fig. 69.1). This sequence causes secretion of preformed primary mediators of anaphylaxis from the cytoplasmic granules of target cells, including histamine, serotonin, eosinophil chemotactic factor of anaphylaxis (ECF-A), heparin, neutrophil chemotactic factor, and proteolytic enzymes that include tryptase [3].

**FIGURE 69.1** Chemical mediator release. When two IgE molecules are bridged by an antigen that is specifically recognized by those IgE molecules, a cascade of transmembrane and intracellular events is triggered. The result is the extrusion of granule contents (mediators) into the extracellular space and elaboration of other, newly formed mediators. Tyrosine kinase appears to be an important...
intramembrane messenger that initiates the intracellular cascades. At least one cascade involves PLC, which mediates calcium influx into the cell and catalyzes hydrolysis of phosphatidylinositol into the secondary messengers 1,4,5-IP₃ and 1,2-DAG. IP₃ plays a role in calcium mobilization; DAG mediates production of arachidonic acid metabolites and activates PKC. PKC, in turn, participates in the fusion of granules within the cell membrane. PLA₂ mediates the conversion of membrane phospholipid into arachidonic acid, resulting in elaboration of prostaglandins and leukotrienes. Ag, antigen; DAG, diacylglycerol; IgE, immunoglobulin E; IP₃, inositol triphosphate; PKC, protein kinase C; PLA₂, phospholipase A₂; PLC, phospholipase C.

The activation–secretion response also stimulates synthesis of kallikrein and newly generated, secondary lipid mediators, which include platelet-activating factor (PAF); prostaglandin D₂ (PGD₂), a product of the cyclooxygenase pathway of arachidonic acid metabolism; and leukotrienes C₄, D₄, and E₄ (LTC₄, LTD₄, and LTE₄, respectively), products of the lipooxygenase pathway of arachidonic acid metabolism [1,3]. Several cytokines are also released after activation, including interleukins (IL-1, IL-2, IL-3, IL-4, IL-5, and IL-6), tumor necrosis factor, endothelin-1, and granulocyte-macrophage colony–stimulating factor [1].

A variety of substances can induce IgE antibody formation and, on subsequent challenge, provoke anaphylactic reactions [9]. The most common substances are drugs, insect venoms, foods, and allergen extracts used in specific immunotherapy (SIT) [9–11]. These and other less common causes of IgE-mediated anaphylaxis are outlined in Table 69.1.

Non–IgE-mediated anaphylaxis occurs when certain ingested or infused substances cause direct mast cell and basophil activation. Clinically significant examples of non–IgE-mediated anaphylaxis are noted in Table 69.2. The administration of blood, serum, or immunoglobulins to patients who are IgA deficient can result in immune complex formation between donor IgA and recipient IgG anti-IgA antibodies [4,12]. These immune complexes fix complement causing activation of the complement cascade with release of the C3a and C5a complement fragments. C3a and C5a are anaphylatoxins and can directly activate mast cells and basophils.

Physiologic Properties of the Chemical Mediators of Anaphylaxis

The most important chemical mediators of anaphylaxis are histamine, cysteinyl leukotrienes (LTC$_4$, LTD$_4$, and LTE$_4$), PAF, and bradykinin. Physiologically, these substances increase arteriolar vasodilatation, enhance capillary permeability, recruit other inflammatory cells, and precipitate bronchoconstriction (reviewed in [13]). The contribution of multiple mediators other than histamine explains the limited benefit of antihistamines alone in treating anaphylaxis.

Histamine (reviewed in [14]) acts to (a) increase capillary permeability by stimulating terminal arteriolar dilatation and contraction of endothelial cells in postcapillary venules, which opens intercellular gaps, and, as a result, causes the development of urticaria and angioedema; (b) increase secretion from nasal and bronchial mucous glands; (c) stimulate contraction of smooth muscle; (d) enhance prostaglandin synthesis; (e) chemotactically modulate eosinophil migration; and (f) regulate
parasympathetic afferent nerve stimulation (a process blocked by atropine), which increases airway resistance and decreases lung compliance. Studies of histamine infusion into normal human volunteers suggest that vasodilatation is mediated by both H_1 and H_2 receptors, whereas bronchoconstriction and tachycardia are mediated by H_1 receptors alone [15].

During an anaphylactic reaction, LTC_4, LTD_4, and LTE_4 (a) induce a prolonged constrictive effect on bronchial smooth muscle, which affects the peripheral more than the central airways, (b) increase vascular permeability, and (c) act as chemotactic agents for other inflammatory cells [16,17]. In fact, leukotrienes are far more potent bronchoconstrictors than is histamine.

Two additional modulators of anaphylaxis are bradykinin, which stimulates a slow, sustained contraction of bronchial and vascular smooth muscles while increasing vascular permeability and secretion from mucous glands, and PAF, which induces platelet aggregation, recruits eosinophils, and can directly increase vascular permeability [3,18].

Thus, the physiologic consequences of chemical mediator release during anaphylaxis are (a) an increased vascular permeability; (b) an increased secretion from nasal and bronchiolar mucous glands; (c) smooth muscle contraction in the blood vessels, the bronchioles, the gastrointestinal tract, and the uterus; (d) migration–attraction of eosinophils and neutrophils; (e) bradykinin generation stimulated by kallikrein substances; and (f) induction of platelet aggregation and degranulation. These events act synergistically to increase the vascular permeability that in turn permits the access of a variety of plasma proteins (antibodies, complement, kinins, and coagulation proteins) to tissue sites, which further contributes to the observed inflammation. Substances such as PAF potentially contribute to local coagulation abnormalities, which may also be seen in anaphylactic reactions [3].
Mast cells are concentrated in the skin, in the mucous membranes of the respiratory and gastrointestinal tracts, and in the perivenular tissue, whereas basophils are located in the bloodstream, all of which are potential sites of exposure to offending antigens (e.g., food, drugs, insect venom, diagnostic agents) [1]. These sites are also most commonly involved in the manifestations of an anaphylactic reaction. Urticaria, angioedema, respiratory obstruction (cough, wheezing, stridor, or breathlessness), and vascular collapse are the most important clinical features of anaphylaxis, and these signs and symptoms are due to the direct effects of mast cell and basophil-derived mediators on affected organ systems. Other clinical manifestations may include (a) a sense of fright or impending doom, (b) weakness or dizziness, (c) sweating, (d) sneezing, (e) rhinorrhea, (f) conjunctivitis, (g) generalized pruritus and swelling, (h) flushing, (i) hypoxemia, (j) choking, (k) dysphagia, (l) vomiting or diarrhea, (m) abdominal pain, (n) incontinence, (o) uterine cramps, and (p) loss of consciousness.

Profound hypotension and shock may develop as a result of significant arteriolar vasodilatation, increased vascular permeability, cardiac arrhythmias, or irreversible cardiac failure, even in the absence of respiratory or other symptoms [3,10]. Furthermore, transient or sustained hypotension may result in local tissue ischemia, stroke, myocardial infarction, or death [10]. Intravascular coagulation, evidenced by a fall in the levels of factors V, VIII, fibrinogen, kininogen, and complement components, has also been described [1].

Anaphylaxis-induced fatalities most often result from involvement of the respiratory tract [19,20]. Structures throughout the respiratory tract may be affected, but respiratory failure is generally the result of upper respiratory tract obstruction due to laryngeal edema or obstruction of small airways due to bronchoconstriction, mucosal edema, and hypersecretion of mucus [21,22]. Intra-alveolar hemorrhage and acute respiratory distress syndrome have been reported [22,23].

The physical examination of a patient with anaphylactic shock may reveal one or more of the following: a rapid, weak, irregular, or unobtainable pulse, tachypnea, respiratory distress, cyanosis, hoarseness, stridor, dysphagia, diminished breath sounds, crackles, cough, wheezes, hyperinflated lungs, urticaria, angioedema, or conjunctival edema (Table 69.3) [24]. A given patient may manifest only a subset of these findings, sometimes only cardiovascular collapse or only stridor and breathlessness.

ECG, electrocardiogram.

Laboratory findings in anaphylaxis are varied. Biochemical
abnormalities in anaphylaxis include elevation of plasma histamine, serum or plasma tryptase, and depression of serum complement components [9,10]. Although these biochemical abnormalities codify our understanding of the pathophysiology of anaphylaxis, they are rarely evaluated in the acute management of clinically established anaphylaxis. Plasma histamine peaks by 15 minutes after the onset of anaphylaxis and returns to baseline by 60 minutes; measurement is generally not feasible unless anaphylaxis develops in the hospital. As discussed in the next section, serum or plasma tryptase may be helpful retrospectively when the diagnosis is uncertain [9,25].

Although there have been no systematic reviews of electrocardiographic findings, reports describe disturbances in rate, rhythm, repolarization, and ectopy [26–28], as well as myocardial infarction [29,30]. Chest radiography may reveal hyperinflation caused by severe bronchoconstriction.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ANAPHYLAXIS

Diagnostic Criteria

Development of the characteristic clinical features of anaphylaxis shortly after exposure to an antigen or other inciting agent usually establishes the diagnosis of an anaphylactic reaction \([2,9,31]\). The setting is often suggestive as well: a patient who has just received an antibiotic or radiographic contrast media infusion or one who presents to the emergency room after a yellow jacket sting. Clinical criteria have been developed to help clinicians recognize the variable presentations of anaphylaxis \([2,31]\). A diagnosis of anaphylaxis is likely when any one of the following three criteria is present: (1) the rapid onset (minutes to several hours) of an illness with involvement of skin and/or mucosa (angioedema, flushing, pruritus, urticaria), and either respiratory compromise (dyspnea, wheeze, decreased peak flow, stridor, hypoxemia) or hypotension or end-organ dysfunction (collapse, syncope, incontinence); (2) onset of two or more of the following features after exposure to a likely allergen: skin and/or mucosa (angioedema, flushing, pruritus, urticaria), respiratory compromise (dyspnea, wheeze, decreased peak flow, stridor, hypoxemia), hypotension or end-organ dysfunction (collapse, syncope, incontinence), or persistent gastrointestinal symptoms (vomiting, crampy abdominal pain, diarrhea); or (3) onset of hypotension minutes to several hours after exposure to a known allergen for that patient \([31]\). Recognition of the early signs and symptoms of anaphylaxis and prompt treatment are imperative to prevent progression to irreversible shock and death \([9]\).

Laboratory Testing

Initial laboratory testing is often not helpful diagnostically, except to exclude other causes of the clinical presentation. However, samples obtained during the acute episode can be assayed subsequently for serum or plasma total tryptase. Total tryptase levels include both \(\alpha\)- and \(\beta\)-tryptase; the former is increased in systemic mastocytosis and the latter can be elevated for up to 6 hours after the onset of a suspected anaphylactic reaction \([25]\). However, the sensitivity of \(\beta\)-tryptase is
suboptimal because levels can be normal after documented anaphylaxis, especially when caused by foods [9]. There may be a role for serial measurements for documenting the course of systemic mast cell and basophil degranulation [9]. As noted above, histamine is rarely assessed clinically because it must be obtained within the first hour after a reaction and requires special handling.

Retrospectively, measurement of antigen (allergen)-specific IgE antibodies by an ImmunoCAP (or similar assay, which have replaced radioallergosorbent tests [RAST]) may be helpful. Specific skin tests may also define allergic sensitivity. Skin testing must be done in a carefully controlled setting due to the risk of provoking a severe reaction. Cutaneous assessment for the presence of antigen-specific IgE may be negative for several days after a reaction because mast cell and basophil degranulation at the time of the initial reaction may lead to a refractory period. This can be avoided by delaying testing for 4 to 6 weeks [32].

**Differential Diagnosis**

Clinical disorders that may be confused with anaphylaxis are sudden, acute bronchoconstriction in an asthmatic, vasovagal syncope, tension pneumothorax, mechanical airway obstruction, pulmonary edema, cardiac arrhythmias, myocardial infarction with cardiogenic shock, aspiration of a food bolus, pulmonary embolism, seizures, acute drug toxicity, septic shock, and toxic shock syndrome [10,31]. Particularly relevant syndromes in the differential diagnosis are the noningestion/medication-triggered urticaria/angioedema disorders—ACEI-induced, idiopathic (spontaneous), hereditary, and acquired. These can present with several of the concerning manifestations of anaphylaxis, including respiratory failure requiring intensive care. While the initial management is similar to that of anaphylaxis, there are several key differentiating clinical and laboratory features to aid in accurate diagnosis. These are discussed in more detail under the “Specific Agents and Precipitants” section later in this chapter.
CLINICAL COURSE OF ANAPHYLACTIC REACTIONS

The constellation of clinical symptoms as well as their severity and duration is variable but will depend to some extent on the mode of antigen exposure. Anaphylaxis may occur within seconds following parenteral introduction of antigen and usually occurs within 30 minutes \[1,9,33\]. In contrast, the onset of anaphylaxis that follows oral administration of an antigen ranges from minutes to several hours \[34\]. In a series of 164 fatal episodes of anaphylaxis, the median time between onset of symptoms and cardiac or respiratory arrest was 5 minutes for iatrogenic anaphylaxis, 15 minutes for stinging insect anaphylaxis, and 30 minutes for food-induced anaphylaxis \[33\].

Generally, the more rapid the onset of symptoms, the more severe will be the reaction \[1\]. Mild systemic reactions often last for several hours, rarely more than 24 hours. Severe manifestations, such as laryngeal edema, bronchoconstriction, and hypotension, if not fatal, may persist or recur for several days. However, even severe manifestations may resolve within minutes of treatment. Up to 20% of patients will experience biphasic or protracted anaphylaxis, with signs and symptoms recurring up to 24 hours or persisting beyond 24 hours after initial presentation \[24\]. This highlights the need for close observation after initial response to treatment.
TREATMENT OF ANAPHYLAXIS

The key to successful treatment of anaphylaxis is prompt intervention to support cardiopulmonary function and effective action to prevent further exposure to the inciting stimulus when possible. The prompt administration of epinephrine is critical and should be supplemented, when needed, with aggressive use of vasopressors, fluid replacement, and medications to counteract the effects of released chemical mediators [9]. Injectable epinephrine, intravenous infusion materials and fluids, antihistamines, intubation equipment, a tracheostomy set, and individuals trained to use these materials should be available. Since symptoms of a systemic anaphylactic reaction may be followed by potentially fatal manifestations, patients must be serially examined and continuously monitored [9]. Many therapeutic and diagnostic agents frequently employed in intensive care settings (e.g., antibiotics, radiographic contrast) may induce anaphylactic reactions. Thus, the anticipation and the preparedness to deal with these potential reactions are very important.

Emergency Measures

The evaluation of individuals who are suspected of having anaphylaxis must be performed rapidly. The cause and mechanism of antigen exposure should be ascertained to assess how long the inciting antigen has been present and, when possible, to limit further absorption (e.g., stopping infusion of a medication or contrast media). Epinephrine should be administered intramuscularly, as soon as anaphylaxis is identified. The patient should be placed in a recumbent position with the legs elevated; pregnant patients may be placed in the left lateral decubitus position if inferior vena cava compression is a concern. Intravenous access with one or two large bore catheters should be achieved for fluid resuscitation.

A history of previous allergic reactions and former treatment may help to guide immediate therapy, obviating the need to try previously failed regimens in a life-threatening situation [35].

Supportive Cardiopulmonary Measures

Particular attention to the respiratory and cardiovascular systems is paramount and must include assessment for laryngeal edema and bronchoconstriction, as well as monitoring of oxygenation, blood pressure, and cardiac rhythm [31].
Ensuring adequate ventilation and oxygenation is essential. Supplemental oxygen should be administered and pulse oximetry monitored. Intubation and assisted ventilation may be necessary for cases of severe bronchoconstriction, and ventilator management strategies such as those used for treatment of acute severe asthma exacerbation may be necessary. These techniques are discussed in Chapters 166 and 172.

Oral or nasal endotracheal intubation is usually feasible, but rarely edema of the tongue, larynx, or vocal cords may obstruct the upper airway and preclude oropharyngeal or nasopharyngeal intubation. To ensure a patent airway in such instances, cricothyroidotomy or tracheotomy may be necessary (see Chapters 8 and 9).

Close electrocardiographic monitoring is indicated because the sequelae of anaphylaxis and its therapy are both potentially arrhythmogenic [9]. Hypotension, acidosis, hypoxia, vasopressors, and bronchodilators are well-described predisposing factors for cardiac arrhythmias (see Chapter 189). Adequate intravenous or intraosseous access should be established as soon as possible, preferably with two 18-gauge or larger peripheral catheters or needles.

### Pharmacologic Therapy

The mainstay of therapy is parenteral epinephrine (adrenaline), which acts on bronchial and cardiac β-receptors, causing bronchial dilatation and both chronotropic and inotropic cardiac stimulation. An equally important effect of epinephrine is stimulation of α-adrenergic receptors on blood vessels, which causes vasoconstriction. This is important for managing anaphylaxis-induced hypotension [31]. In addition, epinephrine increases intracellular levels of cyclic adenosine monophosphate (AMP) and thereby acts to inhibit the activation of tissue-based mast cells and circulating basophils [3,15]. Inhaled β₂-adrenergic agents, such as albuterol (salbutamol), complement the actions of epinephrine by reversing bronchoconstriction and reducing bronchial mucus secretion [9].

Antihistamines, particularly the H₁-receptor blocker diphenhydramine, are useful for treating cutaneous manifestations of anaphylaxis, but are slower in onset than epinephrine and not helpful for hemodynamic compromise. Thus, they are considered adjunctive therapy to epinephrine. Given their beneficial safety profile, they may be administered empirically unless there is a specific contraindication (e.g., known prior hypersensitivity). Glucocorticoids, although not immediately active in anaphylactic shock, are effective pharmacologic agents that are capable of increasing tissue response to β-adrenergic agonists as well as inhibiting basophil activation and phospholipase-mediated generation of
LTC₄, LTD₄, and LTE₄ [1,3].

The guidelines for pharmacologic therapy of anaphylaxis are listed in Table 69.4.

### TABLE 69.4 Treatment of Anaphylaxis in Adults [9,10,31]

**Mandatory and immediate**

**General measures**
- Aqueous epinephrine (1:1,000), 0.2–0.5 mL IM; up to 3 doses at 1- to 5-min intervals
- Tourniquet proximal to antigen injection or sting site
- Aqueous epinephrine (1:1,000), 0.1–0.3 mL infiltrated into antigen injection or sting site (unless anatomic region with terminal circulation, e.g., fingertip)

**For laryngeal obstruction or respiratory arrest**
- Establish airway: endotracheal intubation, cricothyroidotomy, or tracheotomy
- Supplemental oxygen
- Mechanical ventilation

**After clinical appraisal**

**General measures**
- Diphenhydramine, 1.25 mg/kg to maximum of 50 mg, IV or IM
- Aqueous hydrocortisone, 200 mg, or methylprednisolone, 50 mg, IV every 6 h for 24–48 h
- Ranitidine, 150 mg, IV over 3–5 min

**For hypotension**
- Aqueous epinephrine (1:1,000), 1 mL in 500 mL of saline at 0.5–2.0 mL/min, or 1–4 µg/min, preferably by a central
venous line
Normal saline or lactated Ringer solution for volume expansion
Glucagon, if patient is receiving β-blocker therapy and hypotension is refractory, 1–5 mg IV slow bolus, followed by 5–15 mcg/minute IV infusion
For bronchoconstriction
Supplemental oxygen
Albuterol (0.5%), 0.5 mL in 2.5 mL of saline, by nebulizer

D₅W, dextrose in 5% water; IM, intramuscular; IV, intravenous.

Specific Therapy

**Epinephrine.** Epinephrine should be administered first to treat all initial manifestations of anaphylaxis [9,10]. When administered alone, it may reverse rhinitis, urticaria, bronchoconstriction, and hypotension. The failure to administer epinephrine or a delay in its administration may be fatal. The intramuscular (IM) route is recommended on the basis of compelling evidence, both from animal and human studies, that epinephrine is more rapidly absorbed when given intramuscularly rather than subcutaneously (SC) [9,31]. The dose is 0.3 to 0.5 mL of a 1:1,000 dilution (0.3 to 0.5 mg) for adults given IM in the anterolateral thigh and should be repeated in 5 to 15 minutes if improvement is equivocal, usually not more than three times [9].

If shock develops, IM epinephrine is unlikely to be well absorbed. In this setting, epinephrine should be given intravenously: 1 mg (1 mL of a 1:1,000 solution or 10 mL of a 1:10,000 solution) diluted in 1,000 mL of D₅W and infused at a rate of 1 µg per minute, titrating up to a maximum of 10 µg per minute, as needed with continuous electrocardiographic monitoring. Slow continuous infusion is preferred over bolus administration due to an excess risk of toxicity with bolus infusion [36]. If intravenous access is not easily obtained, epinephrine may be given by intraosseous access at the same rate, starting at 1 µg per minute and titrating up to a maximum of 10 µg per minute. Another alternative is to administer epinephrine via endotracheal tube (10 mL of a 1:10,000 solution). If hypotension persists, continuous infusion of a pressor, such as norepinephrine, dopamine, or phenylephrine, is typically initiated (see Chapter 190).
Management of β-Adrenergic Blockade. Preexisting β-adrenergic blockade with noncardioselective or cardioselective agents is another potential cause of refractory anaphylactic shock [37,38]. In the presence of β-blockade, anaphylaxis is characterized by bradycardia with or without atrioventricular nodal delay (in contrast to the usual tachycardia), profound and refractory hypotension, urticaria, and angioedema [37]. Whether β-blockade truly increases the chance of developing anaphylaxis or just the severity is not known. β-Blockade appears to increase anaphylactic mediator synthesis and release, as well as altering end-organ responsiveness. Although α-adrenergic agents may increase in vitro release of mast cell mediators in the presence of β-blockade [39], the drug of first choice for treating anaphylaxis in the presence of β-blockade remains epinephrine [9]. Dopamine, which has combined α, β, and dopaminergic activities, may be useful for shock refractory to epinephrine. The dose of β agonists will likely have to be more than usual to overcome the β-blockade. Several case reports note success in treating refractory shock with glucagon ([off-label] 1–5 mg IV by slow bolus followed by 5–15 microg/minute IV infusion titrated as needed), which is often used in the treatment of β-blocker overdose. Glucagon appears to increase cardiac cyclic AMP independent of β-receptors and to increase heart rate despite β-blockade [37,40].

Bronchodilators. Bronchoconstriction is treated with a nebulized short-acting β-agonist (typically albuterol 2.5 mg in 3 mL [0.083%]), often in addition to parenteral epinephrine, as described above. Nebulizer treatments should be repeated every 15 to 20 minutes until bronchoconstriction abates. Alternatively, albuterol can be administered by continuous nebulization (see chapter on asthma). Methylxanthines are not recommended in hypotensive patients because they may worsen hypotension and cause unpredictable cardiovascular toxicity [1]. Their exact mechanism of action is not well defined, and they are not first-line agents in the treatment of bronchoconstriction.

Volume Resuscitation. Given the distributive nature of shock in anaphylaxis, aggressive volume resuscitation should accompany epinephrine (and other vasoactive medications) when hypotension develops. For adults, normal saline is generally preferred, starting with a rapid infusion of 1 L intravenously, although some patients may require more. If intravenous access cannot be obtained, intraosseous administration of saline is an alternative [31].

If the blood pressure does not improve with pressors and volume
resuscitation, the central venous pressure or ultrasonography may provide guidance regarding the adequacy of fluid resuscitation. For refractory hypotension, serial ultrasonography or pulmonary artery catheterization (see Chapter 19) can help guide further fluid, inotropic, and vasopressor therapy, as outlined in Chapter 190.

**Antihistamines.** Histamine receptor antagonists are considered adjunctive therapies to be administered after epinephrine when needed to relieve itching and hives. Antihistamines are more effective for prevention than in treatment of full-blown anaphylaxis and should never be used as the primary therapy for anaphylactic shock. When administered, parenteral administration is preferred to oral administration. The H₁-receptor-blocker diphenhydramine (1 to 2 mg per kg up to 50 mg for an adult) can be given intravenously as a bolus [1]. The H₂-receptor-blocker ranitidine (150 mg for adults) can be infused over 3 to 5 minutes or given intramuscularly [9]. H₂-receptor-blocking antihistamines prevent the fall in diastolic blood pressure induced by experimental histamine infusion, but the evidence that H₂-receptor-blocking antihistamines are effective in the treatment of anaphylaxis is anecdotal. The H₂-blocker cimetidine has been reported to cause hypotension when given intravenously and should be avoided.

**Glucocorticoids.** Glucocorticoids are not of immediate clinical benefit and are considered adjunctive therapy to epinephrine and not a substitute. They may help to reduce bronchoconstriction and laryngeal edema and provide blood pressure support when used in high doses and for prolonged attacks (see Table 69.4 for recommended doses). When parenteral glucocorticoids are administered, the initial dose is usually methyl prednisolone 1 to 2 mg per kg up to 125 mg (or the equivalent), intravenously. Subsequent dosing is based on the response to initial therapy; methylprednisolone may be continued every 6 to 12 hours for 72 hours in patients with persistent or recurrent symptoms [1,9,31].

Despite the theoretical basis for glucocorticoids preventing late recurrences of anaphylaxis, biphasic anaphylaxis has been reported to occur in 20% of anaphylactic reactions in spite of glucocorticoid therapy [24,41]. In this report, after an initial response to therapy, life-threatening symptoms recurred up to 8 hours later. Whether glucocorticoid therapy helped prevent recurrences after 8 hours is not known. Because of the possibility of a late recurrence, patients should be monitored in the intensive care setting for 8 to 12 hours after resolution of symptoms. Roughly 30% of anaphylaxis cases may have protracted symptoms for 5 to 32 hours despite vigorous therapy including glucocorticoids [24].
PREVENTION OF ANAPHYLACTIC REACTIONS

In view of the potential morbidity and mortality from anaphylactic reactions, prevention is of primary importance. Prevention includes obtaining a careful history to identify possible precipitants of anaphylaxis. Both physicians and patients should be aware of potential cross-reacting agents. For example, individuals with anaphylaxis secondary to aspirin are frequently sensitive to nonsteroidal anti-inflammatory drugs, such as ibuprofen, naproxen, ketorolac, and sulindac. Preservatives, such as metabisulfite, ethylenediamine, and methylparaben, have been associated with anaphylactic reactions. It is therefore helpful to review the inactive ingredients contained in medications temporally associated with anaphylaxis [42]. In some instances, combined precipitants can trigger anaphylaxis, as in food-exercise– or NSAID-exercise–induced anaphylaxis (discussed later), where each precipitant alone does not trigger anaphylaxis but the combined stress, particularly if temporally close, can cause anaphylaxis. Prevention for these settings involves specific recommendations, usually related to adequate time separation of triggers [43].

Prevention of reactions to specific agents (e.g., antibiotics) is discussed below. In general, patients with a history of anaphylaxis should wear emergency alert jewelry, which details offending precipitants and potential cross-reacting agents. In addition, patients should be provided with and instructed in the use of anaphylaxis kits (e.g., EpiPen) for prompt treatment in future reactions. Finally, consultation with an allergist can clarify the offending trigger (if unknown) and guide appropriate evaluation and treatment plans. These three actions are the most relevant elements of postanaphylaxis care from the intensive care perspective.
MANAGEMENT OF ANAPHYLAXIS TO SPECIFIC AGENTS AND PRECIPITANTS

β-Lactam Antibiotic Anaphylaxis

One of the most common causes of anaphylaxis in the United States is penicillin. Systemic reactions complicate approximately 1% to 2% of penicillin courses. Approximately 10% of the population will have positive skin tests to penicillin. Thus, a substantial portion of the population is at risk for developing anaphylactic reactions to the drug. About 10% of these reactions are life threatening, and 2% to 10% are fatal [11]. Seventy-five percent of the patients who die of penicillin anaphylaxis have experienced previous allergic reactions to the drug. As with other medications, the risk of a severe reaction is greater with parenteral administration than with oral administration [11]. On the other hand, about 85% to 90% of individuals who report penicillin allergy are found to be nonallergic on subsequent evaluation [44].

Skin testing for penicillin hypersensitivity with the major determinant benzylpenicilloyl-poly-L-lysine (BPO, PRE-PEN, and ALK-Abello) and minor determinants benzylpenicillin (Pen-G), benzylpenicilloate, and benzylpenilloate is effective for detecting IgE-mediated sensitivity and thereby identifying individuals at risk for developing acute allergic reactions to penicillin [11]. The minor determinant mixture of the above-noted substances is not commercially available, and it is accepted that Pen-G is adequate to represent the minor determinants. The negative predictive value of skin testing when both major and minor determinants of penicillin are used is excellent for immediate hypersensitivity reactions to penicillin [45]. This testing does not evaluate other types of sensitivity, such as serum sickness reactions, morbilliform rashes, hemolytic anemia, and interstitial nephritis. In addition, it does not evaluate patients who may have specific allergy to a β-lactam side chain of a penicillin derivative, for example, cephalosporins or carbapenems [46]. Cross-reactivity between β-lactams and monobactams, for example, aztreonam, is rare. For critically ill patients, who need a β-lactam drug and who have a convincing history of severe β-lactam antibiotic allergy, the best strategy is to use an alternate, non-cross-reacting antibiotic or to proceed with a rapid desensitization protocol. These have become well established in clinical practice and vary slightly from institution to institution. The essentials, as described [11], are a series of infusions of gradually increasing concentrations (hence drug amount) over several hours with observation between infusions ending in infusion of desired/target dose.
of medication. A retrospective review of antibiotic desensitization for IgE-mediated allergy found that it was successful in 75% of patients [47]. Patients with a remote or uncertain history of β-lactam allergy can be considered for a graded challenge: 10% of the target dose administered followed by observation for 30 minutes, and the remainder administered with observation. The benefit of this approach, if applicable, is that a successful graded challenge demonstrates tolerance to the antibiotic, namely, that allergy has been disproved. In contrast, desensitization success does not disprove allergy.

The incidence of anaphylactic reactions to cephalosporins is infrequent but increasing [53]. Patients with a history of penicillin allergy have been reported to have allergic reactions to cephalosporins at a rate of 5.4% to 16.5%, compared with patients with a negative history, whose reaction rate was 1% to 2% [48,49]. The rate of cross-reactivity is lower with second- and third-generation than with first-generation cephalosporins. However, not all of these reactions reflect true cross-reactivity, as only 15% to 40% of patients with a positive history react to penicillin on subsequent testing [48,50]. In a study of 30 patients with immediate-type hypersensitivity reactions to second- and third-generation cephalosporins, 25 of 36 reactions were anaphylactic shock [51]. Only 13% of individuals had either a positive skin test or in vitro evidence of antigen-specific IgE to penicillin determinants, whereas all but three reactions were correlated with a positive skin test to culprit cephalosporins. Unfortunately, skin testing with cephalosporin derivatives is not reliable; severe allergic reactions have occurred in patients with negative cephalosporin skin tests, and cephalosporin antigenic determinants for skin testing have not been standardized. On the other hand, patients with negative penicillin skin tests have no greater risk of allergic reaction to cephalosporins than the general population [49]. Several protocols for desensitization to cephalosporins have been outlined in a review [52]. Cross-reactivity between cephalosporins appears related to the degree of similarity of the R1 side chains; these similarities do not explicitly predict reactivity, but rather guide the choice of an alternate cephalosporin with a different R1 side chain. Ninety percent of patients allergic to second- and third-generation cephalosporins do not react to penicillin derivatives [53].

As noted earlier, monobactams (e.g., aztreonam) do not show cross-reactivity with penicillin, but do show some cross-reactivity with the cephalosporins (i.e., ceftazidime) [53]. Carbapenems (e.g., imipenem, meropenem), in comparison, have historically shown significant in vivo cross-reactivity with penicillin, and desensitization of penicillin-allergic patients was recommended when there was no reasonable alternative [54]. Several highly informative reports from penicillin (PCN) skin test–positive patients have suggested that carbapenems can be given safely to
young [55,56] and adult [57] patients, who have negative skin tests to the proposed carbapenem. In urgent settings and/or where skin testing is not feasible, a graded challenge or desensitization protocol should be employed with the same precautions as if giving the patient penicillin [11].

Food Anaphylaxis

Food allergy occurs among approximately 6% of children and 3.7% of adults [34]; however, fatal anaphylactic reactions are much less common. Due to variable patterns of absorption, biphasic and/or prolonged anaphylaxis occurs in about 20% of cases. However, the delayed phase is rarely associated with a mild acute phase, where hypotension and bronchoconstriction are readily apparent [58]. A review of fatal and severe nonfatal anaphylactic reactions to foods revealed several important features of the fatal anaphylactic reactions: all occurred among patients with asthma, all were in a public setting rather than in the home, and all were associated with delayed or nonadministration of epinephrine [2]. The foods that caused these severe reactions were peanuts, cashews, milk, filberts (hazelnuts), walnuts, and eggs. In another review of the causes of anaphylaxis, the five most common foods were pine nuts, peanuts, soy, shellfish, and other nuts [59]. A survey of food-related anaphylactic fatalities reported to an association registry confirmed the association between asthma and severe anaphylaxis; 90% of fatalities among this group were due to peanuts and tree nuts [20]. A methodical approach to the diagnosis and treatment of food hypersensitivity has been outlined by Sicherer and Sampson [34].

Processed foods may contain significant amounts of milk products, despite a lack of mention of this on the label ingredient lists [60]. This is important to remember for patients with milk allergy who appear to experience a cryptogenic anaphylactic episode. Standards for food labeling instituted in 2006 by the U.S. Food and Drug Administration have assisted patients with food allergy and their providers by requiring identification of possible trace allergen contaminants in processed foods. Other food additives, such as preservatives, have been implicated as causes of anaphylaxis [61]. In the critical care setting, evaluation of likely cause, if cryptic, can begin with serum testing for allergen (food)-specific IgE (ImmunoCAP, others) to a broad range of suspected culprits. However, there is no role for skin testing in the acute setting as skin tests can be negative or misleading in the first 4 to 6 weeks following documented anaphylaxis.
Anesthetic Anaphylaxis

Immediate hypersensitivity reactions to local anesthetics are rare, despite their being one of the most commonly used groups of drugs in medicine [62,63]. Cell-mediated reactions that manifest as contact dermatitis are more common. Local anesthetics are divided into two classes: group I (para-aminobenzoic acid ester) consists of benzocaine, tetracaine, and procaine; group II (non–ester-containing) consists of lidocaine, mepivacaine, dibucaine, and cyclomethycaine. Cross-reactivity between the two groups is very rare, and cross-reactivity between the amides is also rare [64,65]. Skin testing, using a progressive challenge protocol, can help determine whether sensitivity exists and which drugs are likely to be safe in the future [63,65].

General anesthetics, such as neuromuscular blocking agents and thiobarbiturates, also cause anaphylaxis [66]. A skin test protocol has been described for evaluating patients with possible allergy to general anesthetics [67]. Other etiologies of perioperative anaphylaxis include allergy to antibiotics, latex, glutaraldehyde, and opioids.

Since neuromuscular blocking agents are used in intensive care units, anaphylaxis to these agents should be considered in the differential diagnosis of unexplained hypotension in the intensive care unit.

Radiocontrast Media Anaphylaxis

Radiocontrast media studies are frequently necessary in critically ill patients, and so it is important to know when a reaction is likely to occur and how to prevent it. Unfortunately, the likelihood of an anaphylactic reaction to radiocontrast media cannot be predicted by pretesting with oral, conjunctival, or intradermal skin tests [68]. Although the overall adverse reaction rate ranges from 1% to 12% [69], patients with a history of a previous anaphylactic reaction to radiocontrast media have a repeat reaction rate of 35% to 60% [70]. Patients with a general history of allergies, whether to inhalant allergens, foods, or medications, also have an increased reaction rate of serious reactions compared with nonallergic individuals [71]. The majority of contrast media reactions are non-IgE mediated, although evidence is accumulating to suggest that an IgE-mediated mechanism may be contributory in some cases [72,73]. Although exceedingly rare, there have been several confirmed reports of anaphylactic reactions to iodinated oral contrast: Gastrografin (sodium and meglumine diatrizoate), Hypaque (sodium diatrizoate), barium sulfate, and gadolinium [74–78].

Nonionic, low-osmolal radiocontrast agents have largely replaced high-ionic contrast media due to a decreased incidence of overall adverse reactions [79,80], although not all studies have found a reduction in life-
threatening reactions or death [80,81]. Currently, for patients who have had a prior anaphylactic reaction to contrast media and who require a contrast study, the use of nonionic, low-osmolar contrast is recommended in addition to pretreatment with glucocorticoids and, diphenhydramine with or without ephedrine [10,82], as outlined below. Iso-osmolar and noniodinated contrast are also being explored as alternatives to low-osmolar agents [82,83].

Pretreatment protocols have been developed for patients with a history of a prior anaphylactic reaction who require additional intravascular media studies [68,70,84]. In one study of 192 procedures for patients with previous anaphylactic reactions to contrast media, pretreatment with prednisone, 50 mg orally at 13 hours, 7 hours, and 1 hour before the procedure; diphenhydramine, 50 mg orally or intramuscularly at 1 hour before the procedure; and ephedrine, 25 mg orally at 1 hour before the procedure resulted in a reaction rate of 3.1% [70]. A multicenter study of unselected patients receiving intravenous contrast media reported a reaction rate of 5.4% in 2,513 patients given oral methylprednisolone, 32 mg at 12 hours and again at 2 hours before the procedure [84]. In this same study, a single dose of methylprednisolone, 32 mg 2 hours before the procedure, was no better than placebo, with a reaction rate of 9.4% in 1,759 patients. This finding raises the question of how to manage patients with a prior history of anaphylaxis requiring an urgent radiocontrast study. In a small study, 9 such patients were treated with hydrocortisone, 200 mg intravenously immediately and every 4 hours until the procedure was completed, and diphenhydramine, 50 mg intravenously 1 hour before the procedure [85]. Roughly half of the patients received one dose of hydrocortisone, and the other half received two doses. No reactions occurred among these patients. Given that this study evaluated only nine patients, it remains unknown whether additional therapy with ephedrine or an H₂-receptor blocking agent, or both, would provide better protection.

**Latex-Induced Anaphylaxis**

Latex allergy, caused by sensitivity to *Hevea brasiliensis* proteins, can take several forms: contact dermatitis, asthma, urticaria, and anaphylaxis. Perioperative anaphylaxis caused by latex exposure has been described in several children with spina bifida and in patients with a history of multiple surgical procedures [86]. In addition, latex allergy has become an occupational hazard in the health profession since the institution of universal precautions [87]. Sensitivity seems to be increased among atopic individuals with frequent exposure to latex. Unexplained perioperative or nosocomial urticaria, bronchoconstriction, or hypotension should raise concern for latex anaphylaxis. Mucosal and
parenteral exposures have the highest risk of anaphylaxis.

Patients with latex allergy often have cross-sensitivity with certain fruits and vegetables, including banana, kiwi, avocado, chestnut, papaya, potato, and tomato. Latex is found in a wide spectrum of health care products, including elastic thread, rubber bands, condom catheters, Foley catheters, surgical/examination gloves, enema bags, tubing on blood pressure cuffs, rubber stoppers on medication vials and intravenous line tubing, as well as some surgical drapes, drains, and gowns [88–91].

Establishing a diagnosis of latex allergy for a patient who is at high risk on the basis of prior exposures or who may have had latex-induced anaphylaxis is important to guide future prevention efforts. However, skin test extracts are not yet commercially available in the United States and noncommercial latex extracts have been associated with systemic reactions. In addition, the specificity and sensitivity of noncommercial extracts may vary. A preferred alternative is serologic testing by Phadia ImmunoCAP or the Siemens Immulite autoanalyzer; these tests have about 80% sensitivity [90].

The most important steps for the prevention of future anaphylactic reactions to latex are careful patient education and in-hospital latex avoidance through the use of alert bracelets and latex-free kits [66]. Verbal and written information should be provided regarding potential sources of latex exposure and sources of latex-free gloves for patients to take to dentist and doctor visits. In addition, patients should understand the importance of alerting health care professionals who may care for them in the future and the need to carry an EpiPen kit in case of inadvertent exposure.

**Stinging Insect Venom Anaphylaxis**

Venom extracts for yellow jacket, white-faced hornet, yellow-faced hornet, wasp, honeybee, and fire ant are available for skin testing to confirm specific IgE mediation and for desensitization. Results with venom desensitization suggest more than 95% protection against anaphylaxis on subsequent stings [92]. The duration of desensitization therapy necessary for long-term protection is probably 5 years [92,93]. The geographic distribution of fire ants is expanding, making systemic allergic reactions to these insects a growing concern [94].

**Exercise-Induced Anaphylaxis**
Exercise-induced anaphylaxis syndrome is distinct from cold cholinergic urticaria and exercise-induced asthma and usually occurs among individuals who engage in vigorous exercise [43,95]. A subgroup of these patients is allergic to a specific food (wheat is the most common), which acts as a cofactor; manifestations of anaphylaxis only occur if ingestion of the specific food is accompanied by exercise. Other potential cofactors include nonsteroidal anti-inflammatory drugs (NSAIDs), alcoholic beverages, and exposure to high pollen counts [96,97]. Typically, these patients can either ingest the food/NSAID or perform the exercise without adverse effect.

Anaphylaxis can be prevented by delaying exercise by at least 2 and preferably 4 hours after eating (48 hours after ingesting a known food cofactor) and stopping exercise at the onset of pruritus. When NSAIDs are a cofactor, they should not be taken for at least 24 hours before exercise. Exercising with someone who is capable of administering epinephrine is also recommended. Antihistamines and/or leukotriene modifiers (montelukast, zileuton, and others) are occasionally of benefit in prevention.

Idiopathic (Spontaneous) Urticaria/Angioedema/Anaphylaxis

A group of patients has been described who experience recurrent anaphylaxis without an identifiable precipitant, the so-called idiopathic anaphylaxis [98]. In these patients, a careful review of all foods, preservatives, and drugs ingested before the episodes, as well as physical factors such as exercise, fails to reveal a cause for recurrent life-threatening anaphylaxis. These patients should be evaluated for possible systemic mastocytosis [99]. Idiopathic anaphylaxis is most likely on the spectrum of diseases of excess mast cell activity with resultant signs and symptoms of excess histamine release and its consequences, whether from autoantibodies to the high-affinity IgE receptor on mast cells or other unknown triggers [100,101]. These patients can have diffuse hives, angioedema including airway involvement, and typically both. Maintenance therapy is directed at reducing histamine responsiveness as well as oral glucocorticoids, and, in refractory cases, anti-IgE therapy (omalizumab) [102,103]. Second-line additional agents (cyclosporine, dapsone, hydroxychloroquine) have been used in individual patients [104].

Bradykinin/Complement-Mediated Angioedema: Angiotensin-Converting Enzyme Inhibitor, Hereditary, and Acquired
Angiotensin converting enzyme (ACE) inhibitors can cause potentially life-threatening facial and oropharyngeal angioedema [105]. Onset of angioedema usually starts within the first several hours or up to a week after beginning therapy, but angioedema can develop after months to years of asymptomatic usage [106]. Subsequent episodes may recur days to weeks after discontinuation. A late onset of symptoms, 12 to 24 hours after the last dose, has been reported with the long-acting ACE inhibitors lisinopril and enalapril [107]. As with ACE-induced cough, cross-reactivity is the rule among different ACE inhibitors. The mechanism is unknown but is suspected to be related to an alteration in bradykinin metabolism, leading to excess bradykinin and resultant vasodilatation or, possibly, an interaction with components of the complement cascade (e.g., complement 1-esterase inhibitor) [106,108].

Diagnostic testing is not available, and so the diagnosis is made clinically on the basis of the characteristic pattern of angioedema in a patient taking an ACE inhibitor. An important distinguishing feature of bradykinin/complement angioedema is that, as a rule, there is no associated urticaria or pruritus. Treatment includes cessation of ACE inhibitor therapy and assessment and maintenance of airway patency. In general, epinephrine, antihistamines, and systemic glucocorticoids are of minimal benefit, although a few studies have suggested an earlier time to extubation among patients treated with antihistamines. For patients with severe or persistent airway swelling, some studies have reported benefit with agents that are approved for use in hereditary angioedema, such as icatibant (off-label, 30 mg given by slow infusion subcutaneously, may be repeated in 6 hours), fresh frozen plasma (2 units), and purified C1 inhibitor concentrate (off-label, dosing per package insert) [106,108].

Hereditary angioedema (HAE) is the result of dysfunction or low levels of C1 esterase inhibitor, causing unchecked complement activation and (1) excess C3a, C4a, and C5a, and (2) excess bradykinin, resulting in angioedema. The disorder is inherited in an autosomal dominant pattern, but up to 15% of cases are new mutations without ancestral history. Onset of disease is typically in early to late adolescence and is marked with three main types of crises: extremity, facial/airway, and abdominal. Although crises can be spontaneous, trauma is a well-recognized precipitant, specifically for extremity and facial/airway crises. Of particular relevance is the development of facial and airway angioedema within 24 hours after invasive dental work or oral surgery because this can be readily misidentified as local anesthetic allergy since these are usually co-administered in these procedures. Abdominal crises are characterized by subacute or acute onset of crampy abdominal pain associated with nausea and vomiting. Due to bowel wall edema, there is often initial constipation from peristaltic dysfunction, which can be followed by diarrhea. Of note, these patients can present with an acute
abdomen and radiographic findings suggestive of ischemic bowel. Careful clinical judgment is needed because episodes are typically self-limited and abdominal surgery, as a traumatic trigger, could further exacerbate visceral angioedema.

_Acquired angioedema_ (AAE) occurs in the setting of autoimmune disease (e.g., rheumatoid arthritis) or hematologic malignancy, where there is either excess complement component C1 activation or autoantibodies against C1 esterase inhibitor, leading to angioedema from the same downstream mechanisms as in HAE. These patients typically present after their fourth decade of life, in contrast to patients with HAE.

Diagnostic laboratory evaluation is warranted in patients who present with angioedema _without_ urticaria and no clear trigger, especially if there is suggestive underlying autoimmune or lymphoproliferative disorder. In patients with HAE or AAE, complement component C4 is typically decreased at all times, whereas C2 is more typically low during attacks. Tests for quantitative and functional C1 esterase inhibitor should be sent, as well as complement component C1q, as the latter is decreased in AAE but not in HAE. As a rule, C3 levels are of little benefit as they remain normal in HAE/AAE even during attacks, and a low C3 should lead to inquiry of potential comorbid or alternate causes. Of note, a subtype of HAE (HAE-III) has been identified, almost exclusively in women, with a similar clinical presentation as other forms of HAE, but whose laboratory evaluation detailed above is normal. This rare disorder, which is beyond the scope of the current chapter, has been reviewed [105].

Beyond immediate supportive measures, use of epinephrine, antihistamines, and systemic glucocorticoids are of minimal benefit as in ACEI-induced angioedema. Several agents have been approved for use in acute attacks of HAE/AAE focusing on airway crises, including concentrated (plasma-derived) C1 esterase inhibitor (e.g., Berinert, Cinryze), bradykinin B2 receptor antagonists (icatibant [Firazyr]), and kallikrein inhibitor (ecallantide [Kalbitor]) [109]. In the absence of ready availability of these agents, 2 units of fresh frozen plasma [110], with the intent to provide functional exogenous C1 esterase inhibitor, can be used, typically to avert the need to establish an emergency airway for severe laryngeal edema. The approach to treatment of attacks of AAE is similar with respect to clinical assessment and therapeutic measures.

**Aspirin and NSAIDs**

Acetylsalicylic acid (aspirin) and nonsteroidal anti-inflammatory agents
can cause urticaria, flares of urticaria in patients with chronic idiopathic urticaria, anaphylaxis, and aspirin-exacerbated respiratory disease (AERD) [11,111–114]. Most patients have either the urticaria/anaphylaxis pattern or the respiratory disease pattern, but a few patients have both. Some patients with the urticaria/anaphylaxis pattern appear to have sensitivity to a particular NSAID, but most have cross-sensitivity that is related to abnormalities of prostaglandin/leukotriene metabolism [115]. Desensitization protocols for patients with coronary artery disease, who need the antiplatelet effects of aspirin, have been published [116,117].

**Miscellaneous Causes of Anaphylaxis**

Insulin therapy has been associated with an increased risk of anaphylaxis, particularly when a patient on insulin therapy has a history of local wheal-and-flare reactions at the site of insulin injections and interrupts insulin therapy for more than 48 hours and then resumes it [11,118]. Anaphylaxis has also been described with recombinant DNA insulin [119] and to protamine in neutral protamine Hagedorn insulin [120].

The injection of heterologous serum carries a significant risk of anaphylaxis. Human serum (homologous) should be used whenever available. If heterologous serum must be used (antitoxin for snake bites, passive rabies immunization in developing countries, and antilymphocytic serum for organ transplantation), patients are usually evaluated for cutaneous sensitivity by first performing a scratch test with antitoxin or normal horse serum. If there is no reaction, 0.02 mL of a 1:10 serum dilution can be injected intradermally. As with all skin testing, the physician must be prepared to treat any systemic reactions that arise [1].

Patients with mastocytosis appear to be at greater risk for developing anaphylaxis from Hymenoptera stings (even in the absence of IgE mediation) and from mast cell degranulating agents (see Table 69.2). These patients should carry an epinephrine kit during Hymenoptera season. Administration of diagnostic and therapeutic agents that might cause mast cell activation should be avoided in these patients.

The quality of evidence and recommendations for diagnosis and management of anaphylaxis are summarized in Table 69.5.

**TABLE 69.5 Management of Anaphylaxis—Quality of the Evidence**

| History of exposures and timing is the most important |
information to determine whether a set of symptoms was due to anaphylaxis and what tripper precipitated the event. (C)

The appropriate dose of epinephrine should be administered promptly at the onset of anaphylaxis. (A/D)

Intravenous infusion of crystalloid is essential for patients who are unstable or refractory to initial therapy with epinephrine. (B)

**Specific situations**

The extent of allergic cross-reactivity between penicillin and cephalosporins is low. (C)

Aztreonam cross-reacts with ceftazidime by shared R-group side chain. (B)

The three groups at increased risk for latex anaphylaxis are health care workers, children with spina bifida and genitourinary problems, and workers with occupational exposure to latex. (B)

Precautions for latex-allergic patients undergoing anesthesia include avoiding latex gloves, latex blood pressure cuffs, latex tourniquets, latex intravenous tubing ports, and rubber stoppers on vials. (B)

The greatest number of anaphylactic reactions in children has involved peanuts, tree nuts, fish, shellfish, milk, and eggs. (C)

Anaphylactic reactions to foods almost always occur immediately, but may recur hours later. (A)

**Strength of recommendation**

A. Directly based on meta-analysis of randomized controlled trials or from at least one randomized controlled trial or systematic review of randomized controlled trials/body of evidence.

B. Directly based on at least one controlled trial without randomization or at least one other type of quasi-experimental study or extrapolated recommendation from A.

C. Directly based on at least one other type of quasi-experimental or descriptive/comparative study or
extrapolated recommendation from A or B.

D. Directly based on evidence from expert committee report or opinions or clinical experience of respected authorities or both.

Dermatology in the Intensive Care Unit

JULIA BALTZ • KRISTEN BERREBI • DORI GOLDBERG • MARY E. MALONEY • HALEY SNADECKI

INTRODUCTION

Patients in the intensive care unit (ICU) often present with cutaneous findings. Their reason for admission to the ICU may be primarily dermatologic, as in the case of toxic epidermal necrolysis (TEN) or pemphigus vulgaris, two diseases in which large areas of the epidermis are shed. Or they may have skin findings that provide diagnostic clues to their internal disease, as when a patient with systemic lupus erythematosus (SLE) presents with a classic malar rash. Patients with life-threatening infections, such as Rocky Mountain spotted fever (RMSF) and meningococcemia, may present with characteristic skin lesions that suggest the correct diagnosis and allow prompt institution of lifesaving treatment.

Skin conditions in ICU patients are often iatrogenic, being caused by drugs (e.g., TEN, drug reaction with eosinophilia and systemic symptoms [DRESS], acute generalized exanthematous pustulosis [AGEP]), procedures (e.g., cholesterol emboli), dressings (e.g., contact dermatitis), or inattentive care (e.g., pressure ulcers). At other times, patients may have skin conditions which, although relatively minor, may complicate their ICU stay, put other patients and health care workers at risk (e.g., scabies), or make patients uncomfortable (e.g., miliaria, Grover’s disease).

In this chapter, we give an overview of serious illnesses with prominent cutaneous findings, including drug reactions, exfoliative erythrodermas,
infections, blistering disorders, vascular disorders, connective tissue disorders, and graft-versus-host disease (GVHD). In addition, we provide a brief description of more common but less serious dermatoses that may coexist in ICU patients, with suggestions for their management. We emphasize the importance of lesion morphology, that is, the shape, color, size, arrangement, and distribution of skin lesion in making a correct diagnosis. Table 70.1 provides a list of skin diseases arranged by morphology to assist with formulating a differential diagnosis.

• Aphthae
• Trauma

Dermatologic consultation is often helpful for diagnosis and
management of skin diseases of ICU patients. The dermatologic consultant may be able to help sort out multiple potential differential diagnoses by inspection of morphology, skin biopsy, or use of other diagnostic tests (skin scrapings for scabies, potassium hydroxide preparations for fungus, viral and bacterial cultures, and direct fluorescent antibody [DFA] tests for viral infections). Because morphology evolves with the natural course of disease and with attempted therapeutic measures, it is helpful to request consultation early in the course of cutaneous disease.
Cutaneous drug reactions are frequently encountered among ICU patients. Certain drug reactions such as TEN, Stevens–Johnson syndrome (SJS), DRESS, and AGEP may be the primary cause for admission to the ICU. These reactions will be discussed in depth following a brief overview of more commonly occurring drug reactions. The exanthematous or morbilliform drug eruption is the most common (Fig. 70.1). It typically appears 7 to 14 days after introduction of the offending agent. Clinically it appears as symmetric macules that may become slightly papular on the trunk and upper extremities, and may become confluent with time. Low-grade fever and pruritus are sometimes present. The differential diagnosis includes viral exanthem, Kawasaki’s disease, GVHD, and the more serious drug reactions discussed below (TEN, SJS, DRESS, and AGEP). Facial edema, mucosal lesions, blisters or sloughing of the skin, and laboratory abnormalities such as neutrophilia, eosinophilia, and elevated liver function tests may indicate the presence of a more serious drug reaction. Withdrawal of the causative drug is the most important treatment, although topical corticosteroids and oral antihistamines may be used for symptomatic relief. Exanthematous drug eruptions resolve without sequelae 1 to 2 weeks after the offending drug has been discontinued.

**FIGURE 70.1** Morbilliform (maculopapular) drug eruption. Note the pink blanchable papules and plaques with areas of confluence over the trunk and extremities.
Toxic Epidermal Necrolysis/Stevens–Johnson Syndrome

TEN and SJS are entities on a spectrum of severe cutaneous reactions that are most commonly caused by medications. Patients exhibit severe blistering and sloughing of the skin (Fig. 70.2) with mucosal involvement (Fig. 70.3), and can have high morbidity and mortality. The distinction between TEN and SJS is based on the percentage of skin involved with SJS being <10%, TEN being >30%, and SJS/TEN overlap being 10% to 30% of the body surface area affected. The cumulative combined incidence of these entities has been estimated at 2 to 7 per million people annually SJS/TEN occur in all age groups. TEN is more common among women, and incidence increases with age and immunosuppression [1]. HIV infection increases the risk of SJS/TEN with the incidence of TEN in HIV patients receiving trimethoprim–sulfamethoxazole, 8.4 per 100,000 exposures as opposed to 2.6 per 100,000 exposures in non–HIV-infected individuals [2]. Certain human leukocyte antigen (HLA) genotypes render patients more susceptible to SJS/TEN. Currently the FDA recommends HLA-B1502 testing in most East Asian patients prior to prescribing carbamazepine and HLA-B5701 testing on all HIV-positive patients prior to receiving abacavir [3].

**FIGURE 70.2** Toxic epidermal necrolysis. Bullae and sheets of epidermal sloughing leaving behind red denuded areas are seen.
Ninety-five percent of patients with TEN have a history of drug exposure and there is a clear relationship to a drug in 80% of cases. The most common causative medications along with relative risks listed in parentheses include: trimethoprim–sulfamethoxazole (172), carbamazepine (90), nonsteroidal antiinflammatory drugs (NSAIDs) (72), corticosteroids (54), phenytoin (53), allopurinol (52), phenobarbital (45), valproic acid (25), cephalosporins (14), quinolones (10), and aminopenicillins (6.7), with more recent reports implicating lamotrigine, rituximab, imatinib, and lenalidomide [4]. The time from drug ingestion to clinical symptoms is generally 1 to 3 weeks, except for the aromatic anticonvulsants that can take up to 2 months to cause disease [5]. Previous classifications included *Mycoplasma pneumoniae* as a cause of SJS; however, it has been recently proposed that the mucocutaneous eruption associated with *mycoplasma* be considered a separate entity: *Mycoplasma*-induced rash and mucositis (MIRM). Patients with a mucocutaneous *mycoplasma*-associated eruption present with oral mucosal erosions (94%), ocular involvement (82%), and urogenital involvement (63%). Cutaneous involvement is absent among 34% of patients, and targetoid lesions not usually seen. Treatment consists of antibiotics and corticosteroids. Intravenous immunoglobulin (IVIG) is not warranted, as prognosis is excellent with few long-term sequelae [6].
The cutaneous eruption of SJS/TEN may be preceded by a 1- to 3-day prodrome of fever and flu-like symptoms. The initial cutaneous finding is irregularly shaped erythematous to purpuric macules distributed on the face and trunk. These may evolve into flaccid blisters that may be easily enlarged with lateral pressure (Nikolsky sign). The skin can become gray, which usually heralds full thickness epidermal sloughing. Mucosal involvement is present in 90% of patients with SJS and TEN, with the most common affected areas being the conjunctiva, oral cavity, and genitalia. Symptoms include severe skin pain and difficulty swallowing and urinating. Respiratory epithelium may also be involved with resultant dyspnea, pulmonary edema, and hypoxia.

The differential diagnosis includes staphylococcal scalded skin syndrome (SSSS), AGEP, severe acute GVHD, drug-induced linear IgA bullous dermatosis, paraneoplastic pemphigus, and MIRM as discussed above. The appropriate clinical setting and skin biopsy easily differentiate SJS/TEN from these entities. Early lesions demonstrate necrotic keratinocytes, whereas advanced lesions reveal full thickness epidermal necrosis, and a 2005 study found that the density of the dermal mononuclear cell infiltrate correlates with the severity of disease and mortality rate [7].

Prompt diagnosis and rapid cessation of the causative medication along with supportive therapy is the cornerstone of treatment. Careful monitoring of fluid volume, electrolytes, renal function, nutritional status, and evaluation for signs of sepsis should be standard. For extensive body surface involvement, care should be provided in an ICU with staff accustomed to caring for patients with fragile and denuded skin, usually a burn unit. Uninvolved skin should not be manipulated, whereas involved skin should be covered with Vaseline-impregnated gauze and a topical antibiotic ointment. Debridement of necrotic skin may be followed by placement of artificial membranes or biologic dressings such as xenografts or allografts. Bacterial cultures should be performed of involved skin and mucosa as well as blood, urine, and any intravenous catheters, as sepsis is the most common cause of mortality among patients with SJS/TEN. Systemic antibiotics should not be started unless signs of sepsis are present because of the risk of selecting for antibiotic-resistant organisms, and prophylactic use of antibiotics has not been shown to improve outcomes. Patients should be followed by an ophthalmologist for management to prevent conjunctival scarring.

Currently, there is no gold standard systemic therapy for TEN/SJS, as much of the available data are based upon case reports, case series, and small retrospective chart reviews. IVIG has been used, based on its ability to bind Fas receptors, thought to be a mediator, along with granulysin, of apoptosis in TEN/SJS. Unfortunately, there are no randomized double-
blinded trials to support its use, and while some studies have shown mortality benefit with doses more than 1 g/kg/d, others have shown no benefits or even increased mortality associated with its use [8]. Systemic corticosteroid pulse therapy early in the disease course has been shown to have benefits for preventing ocular complications, and topical high potency corticosteroids appear to prevent corneal epithelial stem cell loss and scarring [9]. Furthermore, evidence suggests that high-dose (1.5 mg/kg/d) pulse corticosteroids decreased TEN-associated mortality [10]. There are emerging data supporting the use of cyclosporine as a possibly superior alternative to IVIG [11]. Despite newer data on alternatives, a recent survey study of 111 US burn centers found that IVIG and systemic corticosteroids are the most commonly used therapeutic interventions, with decision to treat based upon the degree and severity of skin/mucosal involvement as well as the likelihood of ongoing infection [10]. Evidence is further clouded because SJS/TEN is a self-limited disease, with maximal detachment occurring at approximately 8 days after the onset of symptoms [8].

The mortality rate for SJS and TEN is 5% and 30%, respectively, and is directly related to the percentage of skin involved. Risk of mortality can be predicted using the Severity of illness SCOR for TEN (SCORTEN) algorithm. One point each is assigned for the presence of the following seven criteria: age >40 years, presence of malignancy, heart rate >120, initial epidermal detachment >10%, serum urea nitrogen >10 mmol per L, serum glucose >14 mmol per L, and serum bicarbonate <20 mmol per L. The points are added and the predicted mortality based upon this total is 0 to 1 (3.2%), 2 (12.1%), 3 (35.8%), 4 (58.3%), and 5 or more (90%) [12]. Healing of sloughed epidermis usually takes 3 weeks; however, survivors may experience delayed ocular scarring and visual loss, necessitating long-term follow-up with ophthalmology. If the causative medication is reintroduced, the disease may recur in less than 48 hours. Notably, a patient who experiences TEN to one class of medication is not predisposed to TEN in response to other medication classes; however, cross-reactivity may be seen between related drug classes such as penicillins and cephalosporins.

**Drug Rash with Eosinophilia and Systemic Symptoms**

Drug rash with eosinophilia and systemic symptoms (DRESS), also called drug-induced hypersensitivity syndrome, is a potentially fatal hypersensitivity reaction to medication, most commonly anticonvulsants [13]. The incidence is between 1/1,000 and 1/10,000 exposures and it is thought to occur with higher frequencies in patients of African ancestry [14].

Although the etiology of DRESS is not understood completely,
alteration in drug detoxification pathways, reactivation of herpesviruses, association with certain HLA alleles and immunologic mechanisms are all implicated in the pathogenesis [15]. DRESS is most commonly caused by the aromatic anticonvulsants, including phenobarbital, phenytoin, and carbamazepine. Of note, these drugs may cross-react. Other common causes include allopurinol, sulfonamides, minocycline, and dapsone. In contrast to other drug reactions, DRESS may develop as late as 4 to 6 weeks after the offending medication has been introduced. DRESS has even been reported to occur more than 1 year after initiating allopurinol. The rash is usually morbilliform, though erythroderma, pustules, vesicles, and purpuric areas may also be present. One study suggested that an erythema multiforme-like eruption may be more indicative of severe hepatic involvement [16].

The hallmark features of DRESS are high fever and edema of the face. Initial systemic involvement may include pharyngitis, lymphadenopathy, hepatosplenomegaly, peripheral eosinophilia, abnormal liver function tests, arthralgias, pulmonary infiltrates, and interstitial nephritis. Liver injury is common and the most common pattern of liver injury is cholestatic type. [17] Circulating atypical lymphocytes may also be present [14]. Certain medications are more commonly associated with specific internal organ involvement [15]. Several case series have shown that high eosinophil count is a poor prognostic factor with other indications of poor prognosis including pancytopenia, thrombocytopenia, and multiple medical comorbidities. Septic shock is a significant cause of mortality in patients with DRESS [18,19]. Late sequelae involving the endocrine system, commonly the thyroid and pancreas, may develop weeks to months after drug withdrawal or rebound during corticosteroid taper. Although end-organ involvement is more common among older patients, young patients are more likely to develop autoimmune sequelae [20]. Fulminant myocarditis is underrecognized and can present initially or months later. One study found ampicillin and minocycline to be the most common medications associated with myocarditis [21].
The most effective treatment is prompt diagnosis and cessation of the offending drug; most patients completely recover after drug withdrawal. A recent study suggests that mild forms of DRESS can be managed without systemic steroids [22] and cutaneous symptoms can be treated with topical steroids. In most cases, other than withdrawing the offending drug, prednisone at 1 mg/kg/d gradually tapered over 3 to 6 months is the current mainstay of treatment. However, there are no controlled clinical trials investigating the risks and benefits of systemic corticosteroids or other systemic treatments [23].

Primary and secondary prevention of DRESS is of utmost importance and one must have knowledge of the most common causative drugs and an understanding of the cross-reactivity among the aromatic hydrocarbons. Mortality rates up to 10% have been reported primarily due to fulminant hepatitis. It is important to monitor for long-term sequelae [23].

**Acute Generalized Exanthematous Pustulosis**

AGEP, also known as toxic pustuloderma [24] or pustular drug rash [25], is a very rare reaction that presents with fever, leukocytosis, and multiple pustules on a background of generalized erythema. AGEP occurs equally in both males and females, and also occurs at any age. Incidence rates have been estimated at 1 to 5 cases per million per year [26].

Drugs are responsible for at least 90% of AGEP cases. In a report of 97 cases from Europe, aminopenicillins (odds ratio [OR] = 23), macrolides (OR = 11), quinolones (OR = 33), hydroxychloroquine (OR = 39), calcium channel blockers (OR = 15), anticonvulsants (OR = 8), and corticosteroids (OR = 12) were the most common causative agents [27]. Patch testing with the offending agent is frequently positive reflecting the dominant role of T cells in the disorder. Although drug-related in the vast majority of cases, there is some evidence showing the reaction is not always related to medication administration. More recently, spider bites have been reported as triggers in addition to possible viral causes [28–30].

The eruption is frequently of sudden onset and the majority of cases appear within 24 hours to several days of exposure to the offending agent. A fever of more than 38°C is followed by the appearance of tiny nonfollicular pustules on a background of generalized erythema and edema. Petechiae, purpura, vesicles, or target lesions may be present, and oral lesions may be observed among 20% of patients. The face and intertriginous areas are the most common presenting locations. Neutrophilia occurs among 90% and eosinophilia among 30% of patients. Liver function tests are usually normal and there is typically no systemic involvement, but lymphadenopathy is sometimes seen. The differential
diagnosis includes pustular psoriasis, subcorneal pustular dermatosis, DRESS, and in severe cases, TEN. An acute onset and clinical history of a new drug favors AGEP over pustular psoriasis, whereas DRESS and TEN exhibit systemic involvement.

Discontinuation of the causative drug is the definitive treatment. Once the diagnosis is made and the causative drug is stopped, the pustules will resolve in less than 15 days with desquamation, and prognosis is excellent. Antipyretics may be used for symptomatic treatment of the fever and topical steroids may be used for symptomatic treatment of the rash, although neither will hasten the resolution of the eruption.
EXFOLIATIVE ERYTHRODERMA

Erythroderma (Fig. 70.4) is a rare, life-threatening skin condition characterized by erythema involving at least 90% of the body surface area with variable degrees of scaling [31–33]. Although age at presentation varies with the underlying cause, patients are typically over 40 or 45 years. Male to female ratio and reported incidence are also variable, and there is no racial predilection [33–35].

The causes of erythroderma may be categorized into preexisting skin conditions (psoriasis, atopic dermatitis, contact dermatitis, and seborrheic dermatitis), drug reactions, malignancy, skin infections and infestations, and idiopathic etiology [31,33]. Over 60 topical and systemic medications have been implicated in erythroderma, including angiotensin-converting enzyme inhibitors, anticonvulsants, penicillin, vancomycin, antifungals, and barbiturates [34,35]. Leukemias and lymphomas constitute up to 40% of malignancy-related erythrodermas. Cutaneous T-cell lymphoma (CTCL) and Sezary syndrome represent most of these cases. Primary blood vessel malignancy and solid organ cancers are also reported in association with erythroderma [35]. Staph scalded skin syndrome (SSSS), HIV seroconversion, superficial dermatophyte and candidal infections, scabies infestation, lupus erythematosus, sarcoidosis, and mastocytosis may rarely cause erythroderma as well. Up
to 46% of cases have no identifiable trigger [31,34].

Varying degrees of scaling, which often begin at flexural surfaces, follow intense widespread erythema within 2 to 6 days. Erythroderma associated with psoriasis and atopic dermatitis has a more indolent course than the more rapidly progressive form linked to malignancy, drugs, and SSSS [34]. Along with intense erythema, patients may have fever, hyperkeratosis of the palms and soles, nail dystrophy, cheilitis, alopecia, edema of the face and legs, dermatopathic lymphadenopathy, hepatomegaly, and splenomegaly [33,34].

Erythrodermic patients have dramatic disturbances in the body’s regulatory mechanisms. Increased cutaneous blood flow results in exaggerated heat and fluid losses with a compensatory increase in the body’s basal metabolic rate. This, in conjunction with the shedding of 20 to 30 g per day of proteinaceous scale, can result in a hypoalbuminemia that exacerbates edema and nutritional deficits [34,35]. Complications include electrolyte imbalance, thermoregulation, dehydration, high output cardiac failure, and secondary infections.

Identification of the underlying trigger is important in the evaluation and management of erythrodermic patients. Early examination of the skin with corroborating evidence from skin biopsy may be helpful in establishing the etiology, but in the majority of adult cases, the underlying dermatosis is obscured by widespread erythema and scaling. Skin biopsy has recently been shown to be more useful in detecting some underlying triggers for infantile and neonatal cases of erythroderma [36].

Erythroderma should be managed as a dermatologic emergency in the inpatient setting. Initial treatment, regardless of the underlying cause, consists of temperature regulation (in spite of the skin being warm or hot to the touch, patients become hypothermic), hemodynamic support and monitoring, and skin care. Topical therapies include low-to-mid potency corticosteroids such as triamcinolone 0.025% to 0.1% or mometasone cream under wet dressings. Tap water–soaked gauze dressings may be changed every 2 to 3 hours, and tepid baths may provide additional relief. As the skin condition improves, emollients can be substituted for corticosteroids. Systemic corticosteroids can be helpful, but must be used with caution in atopic dermatitis and are contraindicated in infection and psoriasis. Additional therapy is targeted to the triggering disease and may include systemic retinoids, cyclosporine, or methotrexate in the case of psoriasis, and psoralen with UVA phototherapy in the case of CTCL [34,35]. Regardless of the underlying cause, relapses of erythroderma are common. Mortality rates range from 4.6% to 64% and are influenced by
advanced age and comorbidities [33].
INFECTIONS

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute febrile illness caused by toxin-producing strains of *Staphylococcus aureus*, presenting with fever, rash, and hypotension, and often progressing to multiorgan failure [37]. A similar syndrome caused by *Streptococcus pyogenes* has also been described, known as streptococcal toxic shock syndrome (STSS) [38]. TSS was originally seen in young women and was associated with tampon use. Although it is now seen in multiple settings, it is still worthwhile to be sure that in menstruating women, a tampon has not been left in place. Pathophysiology of both entities involves massive release of cytokines due to bacterial toxins acting as superantigens.

Both TSS and STSS present with high fever, headache, nausea and vomiting, and myalgias and arthralgias. Hypotension, metabolic acidosis, acute renal failure, elevated transaminases, thrombocytopenia, leukocytosis, disseminated intravascular coagulation (DIC), cardiomyopathy, and acute respiratory distress syndrome (ARDS) are often seen. Most patients with TSS do not have an obvious localized *S. aureus* infection. In contrast, 80% of patients with STSS have a clinically evident painful streptococcal soft tissue infection, often necrotizing fasciitis (NF), usually of an extremity [37].

Skin findings are especially prominent with TSS, which classically presents with generalized macular erythema, but a scarlatiniform rash with accentuation of the flexures can also be seen. Erythema of the palms and soles, conjunctivae, and mucous membranes is also observed. The patient may develop a bright red “strawberry” tongue. The eruption is followed by desquamation 1 to 2 weeks later, especially of the palms and soles.

The differential diagnosis includes RMSF, meningococemia, Kawasaki’s disease, SSSS, scarlet fever, or a medication hypersensitivity reaction. Blood cultures are positive in 60% of cases of STSS, less often in TSS (<15%) [37]. Diagnosis is on clinical grounds and requires four major criteria (fever >38.9°C, erythroderma, desquamation 1 to 2 weeks later, hypotension, and poor peripheral perfusion) and at least three minor criteria (vomiting or diarrhea; severe myalgia or creatine phosphokinase (CPK) twice normal; hyperemic mucous membranes; elevated urea or creatinine; elevated bilirubin, alanine transaminase (ALT), or Aspartate Aminotransferase (AST); platelets <100 × 10^9 per L; and disorientation or altered consciousness). TSS also has a specific T-cell signature with early depletion of the Vβ-2 subset followed by massive expansion, which
can aid in early diagnosis [39]. Skin biopsy shows a neutrophilic and
eosinophilic perivascular and interstitial infiltrate with scattered necrotic
keratinocytes.

Treatment is with supportive care (intravenous fluids and
vasopressors), penicillinase-resistant antibiotics, and IVIG or fresh frozen
plasma (FFP). The current recommendation is that all patients with
suspected TSS and STSS be treated with empiric clindamycin (900 mg IV
every 8 hours) plus vancomycin (15 to 20 mg/kg/dose every 8 to 12
hours) until sensitivities are known. In addition, prompt surgical
exploration and drainage of suspected deep tissue infections is critical in
cases of STSS in which NF may be present.

TSS has a case fatality rate of less than 5%, whereas mortality in STSS
ranges from 30% to 70%, and significant morbidity, including renal
failure, amputation, or hysterectomy may also occur [37,38].

**Cellulitis and Erysipelas**

Cellulitis is an acute bacterial infection of the skin and subcutaneous
tissues. Erysipelas is a more superficial skin infection that involves the
upper dermis and often superficial lymphatics. It is distinguished from
cellulitis and other infections by its very sharply demarcated borders and
induration. Cellulitis is common and more frequently affects men than
women. The lower extremities are most often involved (73% of cases),
followed by the upper extremities (19%), and head and neck (7%) [40].
Cellulitis is usually caused by group A β-hemolytic streptococci or S.
aureus, including methicillin-resistant S. aureus (MRSA) [41], although
it may also be caused by Group B streptococci, *Haemophilus influenzae,
Pseudomonas aeruginosa*, and other bacteria in certain settings.
Infection following aquatic injury is often Gram negative and
polymicrobial, though nontuberculous mycobacterial infections should
also be considered [42]. Erysipelas is almost always caused by Group A
streptococci.

Predisposing factors for cellulitis include venous stasis disease,
lymphedema, lower extremity ulceration, surgical wounds, tinea pedis,
chronic dermatoses, and obesity. Bacteria on the skin surface enter
through breaks in the skin and proliferate in the dermis and
subcutaneous tissues, causing inflammation.

Patients with cellulitis present with poorly demarcated erythema,
swelling, warmth, and tenderness. Cellulitis of the lower extremity
commonly occurs in the setting of leg edema or dermatitis. If a line is
drawn around the involved area, the area of redness is often seen to
spread outward over hours to days. Patients frequently have tender local
lymphadenopathy and/or lymphangitis. Fever or myalgias are sometimes
present. In erysipelas, the skin is bright red and the borders are elevated
Cellulitis has a broad differential diagnosis, including contact dermatitis, superficial thrombophlebitis, deep venous thrombosis, NF, lipodermatosclerosis, and insect bites or stings [43,44]. One of the most commonly confused entities is simple stasis dermatitis, which is usually bilateral with scaling and hyperpigmentation of the distal lower extremities in addition to erythema and swelling. It is usually not tender unless ulceration is present. Cellulitis (particularly “bilateral cellulitis”) is commonly misdiagnosed in the inpatient setting and early involvement of a dermatologist may improve diagnostic accuracy and decrease unnecessary antibiotic use [45].

Diagnosis of cellulitis and erysipelas is generally on clinical grounds. Cultures of blood or cutaneous aspirates and biopsies or swabs are not routinely recommended except in patients with malignancy receiving chemotherapy, neutropenia, cell-mediated immunodeficiency, and history of immersion injury and animal bite [46]. Radiographic studies are usually unnecessary, although plain films or computed tomography (CT) may be of value to evaluate underlying osteomyelitis, and magnetic resonance imaging (MRI) may be used to differentiate cellulitis from NF [43]. If NF is strongly suspected, surgical debridement and intravenous antibiotics should be initiated immediately without waiting for radiologic or microbiologic studies.

Treatment of cellulitis is directed at the most likely bacterial causes, which are streptococci and *S. aureus*. Initial treatment of the hospitalized patient is with β-lactamase-resistant penicillins or cephalosporins such as cefazolin 1 g IV every 6 hours, nafcillin 1 to 1.5 g IV every 4 to 6 hours, or ceftriaxone 1 g IV every 24 hours. Coverage for MRSA should be added if there is evidence of penetrating trauma, MRSA infection elsewhere, nasal colonization with MRSA, injection drug use, signs of sepsis, or if the patient is immunocompromised. Treatment for MRSA can be with IV vancomycin, linezolid, daptomycin, telavancin, or clindamycin and should be started empirically for hospitalized patients with complicated infections [46]. A recent study showed that obese individuals are at risk of clinical failure secondary to inadequate dosing of antimicrobial therapy [47]. As the cellulitis begins to resolve and the patient becomes afebrile, the patient may be converted to oral dicloxacillin or cephalaxin 500 mg every 6 hours, for a total course of 7 to 14 days of antibiotics [43]. Otherwise healthy patients without systemic signs of infection can be treated with oral antibiotics as outpatients.

Local treatment of a cellulitic limb with elevation to reduce swelling
and saline dressings to any open wounds may be helpful. Prognosis of patients with uncomplicated cellulitis is excellent but recurrences can occur. Patients with a chronic tinea pedis as the probable cause of leg cellulitis should have the tinea treated, and venous stasis or lymphedema should be treated with compression stockings or devices to prevent recurrences [43]. A recent randomized control trial showed that treatment of patients with recurrent cellulitis with low-dose penicillin daily was effective for preventing subsequent infections and this should be considered for patients with 3 to 4 episodes of cellulitis per year [46,48].

**Necrotizing Fasciitis**

NF is a rapidly progressive infection involving the subcutis and fascia that typically occurs in the elderly, diabetics, alcohol abusers, cirrhotics, those with chronic cardiac disease or peripheral vascular disease and immunosuppression including cancer, organ transplant, HIV, and neutropenia [49,50]. It is increasing in frequency among young, previously healthy individuals. NF may occur de novo, after surgery and injection therapy or injection drug use, or after penetration or even blunt trauma [51]. The extremity is the usual site of involvement. When NF originates in the scrotum, it is known as Fournier’s gangrene. Most cases result from a polymicrobial infection. Pathogens may include streptococci, *S. aureus*, enterococci, *Escherichia coli*, *Pseudomonas*, *Bacteroides*, and *Clostridium* spp. Community-acquired MRSA has been reported more recently [52]. Invasive Group A *Streptococcus* is implicated in previously healthy patients and has been reported among patients with a history of outpatient liposuction surgery [53]. Other less frequent pathogens include *P. aeruginosa*, *Aeromonas hydrophila*, and *Vibrio vulnificus*, *Haemophilus influenzae* type b.

The skin is initially shiny, erythematous, hot, tender, swollen, and tense. Pain is out of proportion to physical findings. Within 24 to 36 hours, skin color changes from red to dusky gray-blue, and bullae may develop. Deeper soft tissue may feel firm. With the destruction of cutaneous nerves, skin becomes anesthetic. The area becomes gangrenous by the fourth or fifth day, and patients appear toxic with fever, chills, tachycardia, shock, and leukocytosis. NF may be difficult to differentiate from cellulitis, especially early in the course of disease. Features that suggest NF include severe pain which may be out of proportion to physical findings, anesthesia of involved skin, rapid spread, edema and bulla formation, associated varicella infection, signs of shock, elevated creatine phosphokinase level, or NSAID use. NSAID use is implicated in disease progression through attenuation of signs and symptoms of inflammation that leads to a delay of diagnosis.
and treatment. MRI is the preferred diagnostic imaging technique as CT changes may be minimal early on [49]. A newer tool called the laboratory risk indicator for NF uses a scoring system based on C-reactive protein, total white cell count, hemoglobin, sodium, creatinine, and glucose levels to help distinguish between necrotizing soft tissue infections and non-necrotizing infections, and in one retrospective study, was noted to predict mortality and amputation rates [54]. Early fasciotomy and immediate intravenous antimicrobial therapy based on initial Gram stain are crucial. Initial therapy involves vancomycin or linezolid plus either piperacillin–tazobactam, a carbapenem or a both ceftriaxone and metronidazole. Penicillin and clindamycin should be used for the treatment of documented Group A Streptococcus infection [46]. Hyperbaric oxygen therapy for anaerobic Gram-negative infection is controversial. Supportive care and attention to nutrition are important in optimizing postoperative wound healing. Even with early treatment, mortality may be between 9% and 25% [55]. Poor prognostic factors include older age, liver cirrhosis, soft tissue air, aeromonas infection, >10% bands, bacteremia, creatinine >2, peripheral vascular disease, hospital-acquired infection, multifocal disease, and severe sepsis or septic shock on admission [56,57].

**Staphylococcal Scalded Skin Syndrome**

SSSS is a blistering, desquamative skin condition caused by the exfoliative toxins of *S. aureus*. Infants and young children are the most commonly affected, likely because of their immature immune and renal function, resulting in a lack of antitoxin antibodies and accumulation of exfoliative toxin. A few cases have been reported in adults who generally have underlying renal impairment or immunosuppression [58,59]. Two toxins, ETA and ETB, have been detected in human disease, with the majority caused by ETA. These toxins bind to and cleave desmoglein-1, a desmosomal protein in the superficial epidermis critical for binding between keratinocytes. Cleavage of this protein causes separation between keratinocytes in the upper layers of the epidermis and also of the superficial epidermis from deeper layers, with resulting fragile blisters and denuded skin [58,59].

In the localized form of SSSS, bullous impetigo, *S. aureus* enters the skin through a break or tear and introduces exfoliative toxin which results in the development of blisters. Spread of toxin is prevented by antibodies to the toxin. In generalized SSSS, the focus of infection is at a distant site, such as an abscess, pneumonia, osteomyelitis, or endocarditis. Frequently, however, a focus of infection is not found. A lack of protective antibodies allows the toxin to reach the epidermis by hematogenous spread and causes widespread skin disease [58–60].
Whereas bullous impetigo has no associated systemic symptoms, generalized SSSS is associated with a prodrome of fever, malaise, and generalized erythema. This is followed by the formation of large blisters with clear or purulent fluid that easily rupture, leaving extensive areas of denuded skin. The degree of skin involvement may vary from focal blistering to entire body exfoliation. Significant pain and tenderness, hypothermia, fluid losses, secondary infection with *Pseudomonas* and other species, bacteremia, and sepsis may complicate the disease course [58,59].

SSSS should be considered for any presentation of fever and diffuse skin erythema. Although the main differential diagnosis is TEN, other conditions to consider include pemphigus foliaceus, scalding or chemical burns, GVHD, and epidermolysis bullosa. A thorough evaluation should include determination of the degree of denudation, identification of the source of infection, determination of fluid status, and a search for signs of secondary infection. Culture and Gram stain of the skin and focus of infection may identify *S. aureus*, but alone do not confirm the diagnosis of SSSS. Enzyme-linked immunosorbent assay (ELISA) can detect production of exotoxin from isolated *S. aureus* species, but should be used as confirmation of SSSS only, as false negatives can easily result if the pathogenic strain of bacteria is not detected on culture. Blood cultures are frequently positive in adults with SSSS [58,59].

Skin biopsy is the most useful diagnostic test, as it further distinguishes between SSSS and TEN. SSSS shows cleavage in the mid-epidermis with minimal associated inflammation. In TEN, cleavage occurs at the dermoepidermal junction and there is cellular necrosis of the epidermis. TEN can also be distinguished clinically by the presence of mucosal involvement, a finding that is not seen in SSSS. Pemphigus foliaceus, an autoimmune blistering disorder caused by autoantibodies against desmoglein-1, can also be difficult to distinguish both clinically and by routine histology [58,59]. Direct immunofluorescence will demonstrate anti-desmoglein antibodies in the epidermis of pemphigus foliaceus patients [61].

Treatment of generalized SSSS is with intravenous antibiotics targeting penicillin-resistant *S. aureus*. Aminoglycosides may be added if there are signs of secondary infection. Analgesia, fluid resuscitation, and wound care are other key elements of treatment. Use of steroids is contraindicated [58,59].

Exfoliation continues for 24 to 48 hours after institution of appropriate antibiotics. MRSA must be considered for any patient not responding to therapy after this time. Although the disease is rarely fatal in children,
Mortality in adults, even with treatment, is upward of 50% to 60%, when there are serious underlying medical conditions [58, 59].

Meningococcemia

*Neisseria meningitidis* is a major cause of meningitis and sepsis in the United States, with an annual incidence of approximately 1 in 100,000. Meningococcal disease is often rapidly fatal due to shock and multiorgan failure. The majority of cases occur in winter and early spring. Disease peaks in infants and teenagers. Meningococcal disease often occurs in localized outbreaks such as in schools or military barracks [62]. Most affected patients are previously healthy, but those with HIV, immunoglobulin deficiencies, asplenia, or inherited and acquired deficiencies of terminal complement components C5–C9 are at increased risk [62, 63]. *N. meningitidis* is an aerobic Gram-positive diplococcus that only infects humans. Thirteen serotypes have been identified, of which groups A, B, C, Y, and W-135 are the major pathogens. A vaccine against types A, C, Y, and W-135 is available for high-risk individuals. The bacteria inhabit the respiratory mucosa and are spread through respiratory secretions. Virulence factors allow invasion through the respiratory epithelium and into the bloodstream where they damage the endothelium directly and release lipopolysaccharide endotoxin, provoking massive release of tumor necrosis factor α, interleukins-1 and -6, and interferon-γ. These cytokines promote vascular permeability, hypotension, and eventually multiorgan failure and DIC [62, 63].

Mild cases may manifest as a viral syndrome with fever, headache, nausea, vomiting, and arthralgias, whereas in fulminant cases, patients are severely ill with high fever, hypotension, and a hemorrhagic rash. Half of the cases will have meningitis with headache, stiff neck, and photophobia. Cutaneous findings are prominent in as many as 60% of patients with meningococcemia, with petechiae or purpura beginning at points of pressure on the trunk and extremities, spreading to involve any body area. Urticarial and maculopapular lesions may also be observed early in the clinical course. As meningococcemia progresses, large areas of irregular gunmetal gray hemorrhage and necrosis may develop (Fig. 70.5) because of DIC. Among 10% to 20% of children with meningococcemia, purpura fulminans (PF) in combination with multiorgan failure and adrenal hemorrhage, Waterhouse–Friderichsen syndrome, may occur [64].
The differential diagnosis of meningococcemia includes RMSF, leukocytoclastic vasculitis, TSS, erythema multiforme, and other forms of bacterial sepsis. Diagnosis is usually based on blood or cerebrospinal fluid (CSF) cultures, and in cases of meningococcal meningitis, Gram staining of CSF is up to 90% sensitive. Newer polymerase chain reaction (PCR) tests for meningococcus are available, including the IS-1106, nspA, and ctrA TaqMan tests [64, 65]. Because meningococcal sepsis progresses rapidly and has a case fatality rate of up to 40%, treatment should never be delayed pending diagnosis. Prompt treatment is critical. First-line empiric therapy for adults aged 18 to 50 is a broad-spectrum cephalosporin, such as ceftriaxone (2 g IV q12 hours). In adults over 50 years of age, ampicillin is given concomitantly. Once the diagnosis of meningococcemia is confirmed, patients in the United States may be
switched to penicillin G (4 million units IV Q 4 hours), as penicillin-resistant strains are not prevalent [64]. Intensive supportive care with intravenous fluids, pressors, and ventilatory support is usually needed. The prognosis for untreated cases is poor, with 70% dying before antibiotics were available. The overall case fatality of meningococcal disease is now around 10%, though it remains 40% for those with sepsis. Up to 19% of survivors have severe sequelae such as deafness or limb loss [62].

Rocky Mountain Spotted Fever

RMSF is a life-threatening tick-borne febrile illness caused by the intracellular pathogen, *Rickettsia rickettsi*. Despite its name, RMSF is most commonly reported in the Southeast to Midwest states. Cases occur most often in the summer months, when tick exposures are most likely. RMSF is a rare disease, with an annual incidence of seven cases per million, most commonly seen in children. Case fatality rates range from 0.5% to 2.6%, highest on Indian reservations, in the elderly, and the very young. Untreated RMSF has a mortality of 25%, whereas patients receiving appropriate treatment within 5 days of symptom onset have a mortality of 5% [66].

*R. rickettsi*, a pleomorphic coccobacillary obligate intracellular parasite, is transmitted to humans by the American dog tick (*Dermacentor variabilis*) in the Eastern United States and the wood tick (*Dermacentor andersoni*) in the mountain West. *R. rickettsi* infects vascular endothelium and smooth muscle cells where it can replicate and spread to other cells, causing vascular and tissue injury. Vasculitis may occur in the gastrointestinal tract, lungs, kidneys, liver, heart, brain, and skin, leading to multiorgan failure. In addition, *R. rickettsi* promotes the coagulation cascade, leading to hypercoagulability and thrombocytopenia.

Most patients with RMSF present within 14 days of a tick bite with fever and severe headache. Rash usually occurs 2 to 5 days later. Roughly half of all patients will present with the classic triad of fever, rash, and headache. The rash of RMSF is initially blanching pink to red macules on the wrists and ankles, spreading to the palms and soles and then to the arms, legs, and trunk. The face is usually spared. Over several days, the rash becomes purpuric with areas of hemorrhage and necrosis [67]. In addition to fever and headache, patients frequently present with abdominal pain, nausea and vomiting, myalgias, and shortness of breath. Respiratory failure, myocardial edema, renal failure, liver dysfunction,
and altered mental status may occur [68].

The differential diagnosis of RMSF includes other febrile illnesses with rash, such as ehrlichiosis, meningococcemia, TSS, measles, drug fever, idiopathic thrombocytopenic purpura, and various viral syndromes. In cases where no rash occurs, the differential diagnosis would include appendicitis, gastroenteritis, and other causes of acute abdomen. Several diagnostic tests are helpful; however, empiric therapy should be initiated as soon as RMSF is suspected. The indirect fluorescent antibody test for R. rickettsi is 94% sensitive and specific but requires 7 to 14 days to become positive. Skin biopsy shows a lymphohistiocytic vasculitis with extravasation of red blood cells and occasional fibrin thrombi. R. rickettsi may be identified intracellularly by Giemsa staining. Nonspecific laboratory findings include thrombocytopenia and elevated transaminases.

Treatment of RMSF is with doxycycline 100 mg twice daily (or 3 mg per kg of body weight, whichever is higher) for at least 7 days, given orally for outpatients and intravenously for hospitalized patients. Doxycycline should be used even for children (at a dose of 4.4 mg/kg/d divided into BID doses), as the risk of tooth staining has been shown to be quite low for short-term therapy. This regimen will cover other tick-borne illnesses such as Lyme disease and ehrlichiosis. Chloramphenicol (at a dose of 50 to 75 mg/kg/d divided into four doses) is an alternative choice for pregnant women and patients with documented allergy to doxycycline, but is reportedly less effective. Treatment should be continued until the patient has been afebrile for 2 to 3 days [69].

**Disseminated Herpes Simplex Virus Infection**

Herpes simplex virus (HSV), a member of the human herpes virus family, is a common cause of dermatologic disease. HSV-1 and HSV-2 have seroprevalence rates as high as 80% and 25% of US adults, respectively [70].

Infection is spread by close physical contact of mucous membranes or open skin with infected fluids or skin that is actively shedding virus. After initial infection, the virus remains latent in the dorsal root ganglion. Reactivation may be triggered by stress, illness, trauma (such as from intubation), intense UV exposure, and pregnancy. Grouped vesicles on an erythematous base, often with associated pain or pruritus, appear with reactivation. Rupture of vesicles leaves characteristic punched-out ulcers with scalloped edges [70,71]. Infection of immunocompetent patients is self-limited [72]. Immunocompromised patients (HIV, malignancy, medications, or pregnancy) have more frequent and more severe reactivations and there is an increased risk of disseminated cutaneous and visceral disease [72]. Reactivation of genital HSV in
immunocompromised and pregnant individuals is associated with an increased risk of visceral dissemination and high mortality. Patients with disrupted skin secondary to eczema, TEN, burns and other dermatologic diseases including Grover’s disease, Darier disease, and pemphigus vulgaris are at risk of disseminated cutaneous disease known as Kaposi’s varicelliform eruption or eczema herpeticum [70,73]. Patients with vesicular eruptions should be examined carefully for clustered lesions or erosions suspicious of HSV. A high index of suspicion is essential. The differential diagnosis includes herpes zoster, varicella, contact dermatitis, bullous impetigo, and other causes of vesiculation of the skin. Confirmatory tests include Tzanck smear, DFA, viral culture, PCR, and ELISA. All studies are most sensitive when performed on vesicles less than 48 hours old. DFA and culture should be performed together to increase sensitivity from approximately 50% for each alone, to almost 80% [74]. PCR is the most sensitive test, but it is not always available. Although there are no controlled studies for treatment of disseminated disease and no evidence that treatment decreases mortality, intravenous acyclovir at 8 to 10 mg per kg every 8 hours for 7 to 10 days is generally employed [71]. The dose is adjusted for patients with renal insufficiency. Alternatives for acyclovir-resistant cases include foscarnet, vidarabine, and cidofovir [72]. Secondary bacterial infection may complicate the course of HSV infection and should be treated with appropriate antibiotic therapy.

**Disseminated Herpes Zoster**

Varicella zoster virus (VZV) causes both chicken pox (varicella), representing a primary infection, and shingles (zoster), a manifestation of reactivated latent infection. After initial exposure, the virus remains dormant in the dorsal root ganglion] or in cranial nerve root ganglia [75]. Medications, aging, malignancy, bone marrow transplantation, organ transplantation, HIV, rheumatologic disease, and poor nutrition can affect immune status and thereby increase the risk of reactivation. Since the introduction of the herpes zoster vaccine for patients over the age of 60 who are not immunosuppressed, the incidence of VZV infection in the United States has decreased by up to 90% [76].

Upon reactivation, VZV tracks along sensory nerves to affect a particular dermatome, most commonly the ophthalmic division of the trigeminal nerve (V1) and the thoracic dermatome. A prodrome of pain, pruritus, and paresthesia in the affected dermatome is noted by up to half
of the patients. This is followed by an eruption of erythematous macules and/or papules. Over 24 hours, the lesions begin to vesiculate, and over the next 48 to 72 hours, crust over. Pain is the most common symptom, present in 90% to 95% of patients. Prior to the onset of skin lesions, involvement of the thoracic dermatome may be mistaken for acute coronary syndrome.

Immunocompromised hosts may have atypical presentations with unusual lesion morphology, distribution, greater ulceration, and dissemination. Disseminated zoster occurs among 2% of the general population and has been observed in as many as 35% of hospitalized immunocompromised patients. Disseminated zoster is seven times more frequent among patients with HIV and patients with disseminated zoster should be tested for HIV [75]. Disseminated disease presents 7 to 14 days after classical dermatomal zoster and is defined as more than 20 lesions outside the primary dermatome, in either multiple contiguous or noncontiguous dermatomes. Visceral dissemination can involve the lung, liver, and brain [77]. Cases of VZV reactivation and visceral dissemination without cutaneous lesions have been rarely reported [75,78].

Uveitis, keratitis, corneal ulcers, and blindness may result from reactivation along the ophthalmic division of the trigeminal nerve. Myelitis or encephalitis may result in weakness and altered mental status. Rarely, motor nerves may be involved with resulting weakness [75]. Patients are contagious until lesions become crusted. Transmission is via direct contact or airborne from respiratory secretions or aerosolized skin lesions. Airborne transmission is more likely among patients with disseminated disease and these patients should be under strict isolation precautions [79].

Differential diagnosis includes HSV infections, bullous drug eruption, contact dermatitis, and erythema multiforme. Tzanck smear cannot differentiate VZV from other herpesviruses and has a limited sensitivity; therefore, it should not be used to rule out disease [75]. PCR for viral DNA is the most sensitive and specific diagnostic test and can be performed on vesicular fluid, crusted lesions, blood, plasma, CSF, and bronchoalveolar lavage. PCR results take about 1 day to result. DFA testing is performed on scrapings from non-crusted vesicular lesions, has a high sensitivity (90%) and specificity (95%), and results can return in several hours where available. The sensitivity of viral culture is poor and serologic testing is not helpful in an acute setting [80]. Treatment should not be delayed pending results. Patients should be treated if they present within 1 week of onset of their lesions or if they still have any lesions that have not crusted over [77].

Oral acyclovir or valacyclovir is appropriate for healthy individuals who can take oral treatment and for uncomplicated cases of
immunocompromised patients. The dosing regimen is 1 g of valacyclovir or 500 mg of famciclovir every 8 hours, or acyclovir 800 mg 5 times a day, with dose adjustment for renal insufficiency. The duration of treatment is 7 to 10 days. IV acyclovir is the treatment of choice for immunocompromised patients with ophthalmic, disseminated, or HIV-associated disease or those with significant comorbidities [75,77]. Acyclovir resistance is more prevalent among immunocompromised populations and should be suspected if new lesions are forming on acyclovir or a related drug (famciclovir, valacyclovir). Viral sensitivities should be checked in this setting. Resistant strains are treated with foscarnet, 180 mg/kg/d divided into two or three doses and renally adjusted [77]. Central nervous system (CNS), ophthalmologic, or atypical cutaneous presentations should trigger neurology, ophthalmology, and dermatology consultation [75,77]. The mortality for disseminated zoster is between 5% and 15% with most deaths attributable to pneumonia [81].
BLISTERING DISEASES

Pemphigus vulgaris, paraneoplastic pemphigus, and bullous pemphigoid (BP) are autoimmune blistering disorders characterized by autoantibodies directed at cell–cell adhesion molecules or components of the basement membrane zone.

Pemphigus Vulgaris

Pemphigus vulgaris is a rare but potentially fatal bullous disorder that affects the skin and mucous membranes. The worldwide incidence is 0.76 to 5 per million population. However, the incidence is much higher in those of Jewish ancestry [82]. Pemphigus typically affects middle-aged or older individuals. It is caused by autoantibodies against the desmosomal proteins, desmoglein 1 and 3, which are required to maintain cellular adhesion between keratinocytes in the epidermis.

The presenting sign of pemphigus is usually painful oral lesions that occur in virtually all patients. Hoarseness and dysphagia may be a sign of pharyngeal and esophageal involvement, respectively. Mucosal and laryngeal involvement can make intubation and endotracheal tube maintenance more difficult. Cutaneous lesions develop in more than half of the patients, usually after the onset of oral erosions, with fragile vesicles or bullae that rupture easily as blistering is confirmed to the epidermis. Consequently, it is more likely to encounter erosions rather than intact blisters on the skin. Blistering may be induced by rubbing intact, normal appearing skin adjacent to areas of blistering, a phenomenon known as the Nikolsky sign. Extensive loss of epidermal barrier function in pemphigus may be complicated further by secondary systemic bacterial infection and fluid loss.

For patients with only oral disease, the differential diagnosis includes oral HSV, aphthous ulcers, oral lichen planus, and SLE. With cutaneous disease, further consideration should be given to bullous impetigo, bullous drug eruptions, and other autoimmune blistering disorders. Drug-induced pemphigus has been associated with the use of various medications, in particular penicillamine and captopril [82].

Diagnosis of pemphigus is made by routine histology, which demonstrates loss of cell–cell adhesion of keratinocytes (acantholysis) and retained attachment of basal cells to the basement membrane along the dermal–epidermal junction. Immunofluorescence of perilesional tissue shows intercellular deposits of IgG. Serum sent for indirect immunofluorescence or ELISA assays will demonstrate circulating antibodies, and titers in pemphigus usually correlate with disease activity.
Standard treatment of pemphigus is oral prednisone at 1 to 1.5 mg/kg/d. Studies of corticosteroid-sparing agents for pemphigus, including azathioprine, mycophenolate mofetil, cyclosporine, cyclophosphamide, and IVIG, are reviewed in Table 70.2 [83–89]. Rituximab has been observed to be beneficial in refractory pemphigus and has been reported to be effective as an adjuvant to topical corticosteroid [90]. A recent randomized controlled trial showed infliximab was not effective in the treatment of pemphigus [91]. Overall, the optimal therapeutic strategy still has not been established [92]. Most patients require maintenance treatment for sustained remission. Prior to treatment with oral corticosteroids, most patients died within 5 years of disease onset. Current mortality rate is about 5% to 15%, mostly due to complications from immunosuppressive therapy such as sepsis [82].

Comparison of four treatment regimens for pemphigus vulgaris: prednisolone alone, prednisolone plus azathioprine, prednisolone plus mycophenolate mofetil, and prednisolone plus intravenous cyclophosphamide pulse therapy

2007 Randomized, controlled open-label trial over 1 y 120 (30 patients/arm) Efficacy of prednisolone is enhanced when combined with cytotoxic agent. Azathioprine was found to be the most efficacious cytotoxic drug to reduce steroid, followed by cyclophosphamide and mycophenolate mofetil.

Comparison of oral methylprednisolone plus azathioprine or mycophenolate mofetil

2006 Prospective, multicenter, randomized, non-blinded trial 33 Azathioprine and mycophenolate mofetil have similar efficacy, corticosteroid-sparing effects, and safety profiles as adjuvant treatments.

High-dose intravenous immunoglobulin (IVIG) over 5 consecutive days in patients relatively resistant to systemic steroids

2009 Multicenter, randomized, placebo-controlled, double-blind trial 61 (includes pemphigus foliaceus) IVIG (400 mg/kg/d for 5 d) is safe and effective for relatively steroid-resistant patients.

Dapsone versus placebo in patients already on conventional systemic steroids

2008 Multicenter, randomized, placebo-controlled, double-blind trial 19 “Trend to efficacy” of dapsone but not statistically significant.

Cyclosporine as adjuvant to systemic corticosteroids

2000 Concurrently randomized trial 29 Cyclosporine ineffective as adjuvant to corticosteroids.
Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a variant of pemphigus associated with benign or malignant neoplasms. Most commonly associated conditions include non-Hodgkin’s lymphoma, chronic lymphocytic leukemia, Castleman’s disease, thymoma, sarcoma, and Waldenstrom’s macroglobulinemia. Autoantibodies in paraneoplastic pemphigus are directed against a variety of proteins including desmogleins 1 and 3, bullous pemphigoid antigen 230, as well as the plakin family of proteins [93]. For diagnosis, the detection of autoantibodies against envoplakin and periplakin, or α2-macroglobulin-like-1 protein by immunoprecipitation are 95% sensitive, whereas the combination of rat bladder indirect immunofluorescence and immunoblotting is 100% sensitive and specific [94].

The disease usually presents with a recalcitrant stomatitis involving the mouth and characteristically, the lips. Other mucous membranes, including the eyes, genitalia, nasopharynx, and esophagus, may be involved. Cutaneous lesions are polymorphous and may resemble pemphigus vulgaris, BP, erythema multiforme, or lichen planus. Some patients develop bronchiolitis obliterans, which may be fatal as a result of respiratory failure [93]. Two-thirds of patients diagnosed with paraneoplastic pemphigus have a known underlying neoplasm. In the other third, mucocutaneous disease precedes the diagnosis of an associated neoplasm, and these patients must be carefully followed. Severe, intractable stomatitis is a clue for differentiating paraneoplastic pemphigus from other bullous disorders. Disease associated with benign neoplasms such as thymoma or Castleman’s disease may improve or clear completely with treatment of the underlying condition, but the course of disease and prognosis in malignancy-associated paraneoplastic pemphigus is poor. The stomatitis is often refractory to treatment with corticosteroids and immunosuppressants [93]. Patients with extensive skin involvement who present with erythema multiforme–like skin lesions and histologic keratinocyte necrosis often have more severe disease which can rapidly become fatal. These patients must be managed particularly carefully [95].

Bullous Pemphigoid

BP is a chronic subepidermal blistering disorder most prevalent in the elderly, with an incidence of 6 to 7 cases per million. BP often requires
long-term use of immunosuppressive agents, which can lead to both morbidity and mortality. BP is characterized as an autoimmune blistersing disease. The subepidermal blisters in BP result from autoantibodies directed against the hemidesmosomal proteins BP180 and BP230, located at the epidermal–dermal junction. BP is thought to be induced by an environmental stimulus in genetically predisposed individuals. Viral triggers have been postulated and BP may be induced by medications, the most common of which are penicillamine and furosemide [96].

BP has a variety of clinical manifestations, including a nonbullous prodromal phase characterized by severe pruritus, either alone or associated with excoriated eczematous or urticarial lesions. The bullous phase is characterized by tense vesicles and bullae on normal or erythematous skin. Unlike pemphigus, numerous blisters in BP are found intact. The lesions are frequently symmetrical and are most commonly found in flexural areas on the limbs, the lower trunk, and abdomen. The oral mucosa is involved in 10% to 30% of patients [97].

The differential diagnosis includes pemphigus, bullous lupus erythematosus, dermatitis herpetiformis, bullous erythema multiforme, cicatricial pemphigoid, linear IgA dermatosis, and epidermolysis bullosa acquisita. Diagnosis is made by skin biopsy from the edge of a blister, which shows a subepidermal blister with an eosinophil-rich dermal inflammatory infiltrate. Direct immunofluorescence of perilesional skin shows linear deposits of IgG and/or C3 along the basement membrane zone. Indirect immunofluorescence will detect circulating autoantibodies in 60% to 80% of patients [97].

BP has a tendency toward remission and can be controlled more easily than pemphigus. Treatment with high potency topical corticosteroids has been proven effective with fewer side effects than oral corticosteroids [98]. Other immunosuppressive agents such as azathioprine, mycophenolate mofetil, cyclophosphamide, and methotrexate may be added for recalcitrant cases or for steroid sparing in patients with long-term disease. The combination of nicotinamide and minocycline or tetracycline has been successful in small case series. Dapsone, IVIG, plasmapheresis, and extracorporeal photopheresis have been reported to be effective, and rituximab has shown promise for recalcitrant disease in multiple case series [99].
Cutaneous Vasculitis

Vasculitis is defined by inflammation of the blood vessel wall and may involve any sized vessel. As medium vessel vasculitides (polyarteritis nodosa, Wegener’s granulomatosis, Churg–Strauss syndrome) are covered in more depth in Chapter 196, the present discussion will focus on cutaneous small vessel vasculitis (CSVV) and cutaneous findings in other types of medium and large vasculitis.

CSVV may be limited to the skin, or there may be multiorgan involvement most commonly involving the kidneys, the gastrointestinal tract, and/or the joints. It is important to recognize that skin involvement may be a sign of more serious internal organ involvement. The pathogenesis involves immune complex deposition in the affected vessel walls triggering the activation of complement.

Vasculitis may be secondary to infections (15% to 20%), medications (10% to 15%), malignancy (2% to 5%), or autoimmune connective tissue disease and inflammatory disorders including inflammatory bowel disease, cryoglobulinemia (CG), Anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis and Behçet’s syndrome (15% to 20%).

Henoch–Söhnlein purpura (HSP) is a specific subtype of IgA-mediated vasculitis [100,101]. Commonly associated infections include streptococcal and other bacterial acute respiratory infections, bacterial endocarditis, gonococccemia, chronic meningococcemia, hepatitis B and C, HIV, cytomegalovirus (CMV), and mycobacteria. Implicated medications include antibiotics (especially β lactams, sulfonamides, and minocycline), allopurinol, thiazide diuretics, hydantoins, propylthiouracil, NSAIDs, granulocyte macrophage colony stimulating factor (GM-CSF), and anti-tumor necrosis factor (TNF) agents. Malignancies associated with vasculitis include lymphoproliferative, hematologic, and solid organ cancers. Among connective tissue diseases, SLE, rheumatoid arthritis and Sjogren’s syndrome are commonly complicated by cutaneous vasculitis [101]. Levamisole-adulterated cocaine is an increasingly common cause of cutaneous vasculitis that commonly presents with purpura of the ears, retiform purpura of the trunk, neutropenia and a positive P-ANCA [102]. More recently, alcohol has been implicated as a potential cause of cutaneous vasculitis presenting with palpable purpura on the lower extremities several hours after consumption [103]. The underlying etiology may remain unidentified in up to 50% of patients [100].

The skin findings of vasculitis correlate with the size of vessels
involved. The morphologic hallmark of CSVV is palpable purpura. Red to purple, non-blanching macules and papules are concentrated over dependent areas of the skin such as the ankles and lower legs (Fig. 70.6), or over pressure areas such as the buttocks. There may be significant associated edema. Other morphologies include urticarial lesions, which, unlike hives, last more than 24 hours. Patients may be asymptomatic or have burning, pruritus or pain and associated constitutional symptoms and arthralgias. Cutaneous lesions usually occur within 7 to 10 days of exposure to a drug or infectious trigger and 6 months after the onset of an underlying medical condition, though this is variable. Although most cases of CSVV affect only the skin, further consideration should be given to rule out systemic involvement. HSP is an IgA-mediated CSVV that may have associated abdominal pain, gastrointestinal (GI) bleeding, arthritis, and glomerulonephritis. The initial workup of CSVV without an obvious cause includes complete blood count (CBC), basic metabolic panel (BMP), urinalysis, liver function tests (LTFs), hepatitis studies, HIV test, antistrepトolysin O (ASO), anti-nuclear antibody (ANA) and rheumatoid factor (RF) and stool Hemoccult blood testing. Further evaluation, treatment, and specialist referral is guided by laboratory findings.

**FIGURE 70.6** Vasculitis. Nonblanching, red to purple papules and plaques over the legs associated with edema.

Histopathologic evaluation is important for diagnosis and early lesions are most revealing on biopsy. Thus, timely consultation of the dermatology service is important. Along with determining the size of vessel disease, microscopic evaluation of tissue vessels distinguishes
inflammatory from noninflammatory vessel disease. Furthermore, immunofluorescence studies of sampled tissue may help confirm a diagnosis of IgA vasculitis associated with HSP. Patients with HSP need ongoing monitoring of blood pressure and renal function as delayed-onset kidney involvement can occur. It is important to consider coagulopathies and other occlusive vascular diseases in the differential diagnosis of vasculitis as the management of noninflammatory vessel disease differs from that of vasculitis. Purpura, livedo reticularis, ulcers, and necrosis are manifestations of coagulopathies such as immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, drug-induced thrombocytopenia, inherited platelet dysfunction, warfarin and heparin necrosis, DIC, gammopathies, protein C and S deficiencies, and the antiphospholipid syndrome. In bland occlusive disorders in which vessels may be occluded by fibrin, cryoglobulins, or emboli, the purpura may be palpatble as in leukocytoclastic vasculitis, so the clinical distinction is not always apparent.

Treatment is directed at the underlying etiology and preventing the progression of inflammation. It is always important to evaluate and treat any underlying cause, whether it is infection, malignancy, or a drug toxicity. With early intervention, morbidity and mortality from vasculitis may be reduced. For disease limited to the skin, supportive care with rest, leg elevation, topical steroids, and analgesics is usually sufficient. The eruption typically resolves over weeks with hyperpigmentation. It is important to monitor for systemic disease, even after the cutaneous signs have resolved. NSAIDs, colchicine, dapsone, or prednisone can be helpful for patients with recalcitrant or progressive skin disease. Severe intractable skin disease or involvement of organs other than the skin may require immunosuppressive therapy with high-dose prednisone 1 to 2 mg/kg/d, sometimes with steroid-sparing support from methotrexate, cyclosporine, azathioprine, cyclophosphamide, or mycophenolate mofetil [101].

Disorders with large vessel vasculitis are usually diagnosed when bruits, asymmetric pulses, claudication, or neurologic deficits are present. Some patients also have cutaneous findings that serve as clues to underlying pathology. In giant cell arteritis (GCA), the temporal artery is tender, swollen, indurated, or pulseless. The tongue may be tender, atrophic, swollen, or cyanotic. Rarely, patients with GCA may have tender nodules overlying other superficial arteries. In less than 20% of cases of Takayasu’s arteritis, erythema nodosum–like nodules or pyoderma gangrenosum–like ulcers may be present. Cutaneous findings, although
present in 80% of patients, are nonspecific in Kawasaki’s disease, a syndrome associated with coronary artery aneurysms in 12% of affected children. The eruption of Kawasaki’s disease is polymorphous, and patients may present with macules, papules, wheals, targetoid plaques, papulovesicles, pustules, or a scarlatiniform eruption most commonly on the abdomen, groin, perineum, and buttocks. There is often desquamation of the fingertips and mucous membrane involvement may include conjunctival injection, dryness of the lips, erythema of the mouth, and prominent tongue papillae (strawberry tongue). Most patients have enlarged cervical lymph nodes and high fever.

**Purpura Fulminans**

PF is characterized by extensive purpura and necrosis of the skin associated with fever, DIC, sepsis, and hypotension. PF is seen mostly in three clinical settings: acute infections, inherited or acquired coagulopathies, and idiopathic. Meningococcemia, in which 3% of cases develop PF, is the most commonly associated infection. Varicella and pneumococcal sepsis are less frequently associated and rare or isolated reports include *H. influenzae* [105] and other organisms. Asplenism is a risk factor for infection associated with PF. PF in the newborn period is usually due to an inherited coagulopathy and results in high mortality. PF has also been reported in association with acquired coagulopathies seen in inflammatory bowel disease [106,107]. Idiopathic disease is the mildest variant [108–110].

The pathophysiology of PF depends on the underlying trigger. The common end point is that of extensive microvascular thrombosis that affects cutaneous and visceral blood supply. In meningococcemia, endotoxin results in release of cytokines and activation of coagulation pathways, and infection is associated with substantially decreased levels of protein C [108].

Initially in PF, there is pain and erythema of affected areas. Irregular areas of blue–black or dusky discoloration develop within the center of erythematous patches, and lesional skin becomes indurated. There is progression to hemorrhagic vesicles and bullae, and finally to tissue necrosis. Lesions associated with infection tend to involve distal parts first and spread proximally, whereas idiopathic and coagulopathy-associated disease may remain localized to the lower extremities. Idiopathic PF usually affects only the skin; however, other forms may result in widespread necrosis with multiorgan failure. Disease complications include scarring, secondary infections, digital or limb necrosis, and autoamputation [108–110].

The differential diagnosis of PF includes HSP and postinfectious thrombocytopenic purpura, although these are both associated with
milder disease than that seen in PF. The presence of DIC helps
distinguish PF from other causes of cutaneous necrosis [109].

Early recognition of disease and identification of the underlying trigger
is essential in this rapidly progressive condition. Appropriate
antimicrobials are instituted for infection. Supportive care includes
aggressive fluid resuscitation, electrolyte monitoring, and replacement of
blood products. If deficient, protein C and antithrombin III may be
replaced. Other treatment options include FFP, heparin, plasmapheresis,
topical nitroglycerin (for local vasodilation), and recombinant tissue
plasminogen activator [109]. Surgical consultation may be necessary for
debridement and grafting.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (APS) is characterized by a
hypercoagulable state with venous or arterial thrombosis, recurrent fetal
loss, thrombocytopenia, and elevated titers of the antiphospholipid
antibodies (anticardiolipin antibodies, lupus anticoagulant, anti-β-2
glycoprotein I antibodies). Up to 2% of the normal population exhibits
detectable titers of these antibodies and 0.2% have elevated titers. APS
may be primary, or it may be seen in conjunction with SLE, malignancy,
drug toxicity, infection, or hematologic disease [111–113].

Cutaneous manifestations in APS, although highly variable, are
common and often the presenting sign of disease. Recognition of these
findings is therefore essential for early diagnosis and prompt evaluation
for more extensive disease. Skin lesions are thought to be a direct result
of arterial or venous occlusion and subsequent ischemia. The most
common finding is livedo reticularis or livedo racemosa, seen in up to
40% of patients, and up to 70% of patients who have systemic lupus.
These present as a netlike pattern of dusky erythema often found on the
upper or lower extremities; they are thought to be more common in cases
with underlying arterial disease and are less often seen in venoocclusive
disease [114]. Other associated findings include cyanotic macules,
echymosis and purpura, ulcerations of the ears, face, and legs, porcelain-
white scars (atrophie blanche) at the ankles, thrombophlebitis, Raynaud’s
phenomenon, digital ischemia, and gangrene. Any major organ system
can be affected by thrombosis [111–113]. A highly morbid variant,
catastrophic APS, is characterized by thrombosis of multiple organs
developing over a short period of time. Standard therapy is IVIG or
plasma exchange, anticoagulation, and corticosteroids (see Chapter 68
for a more detailed discussion) [115].
The differential diagnosis of APS includes other disorders with associated livedo reticularis and cutaneous necrosis including vasculitis, warfarin-induced skin necrosis (WISN), cholesterol emboli, and CG. Similar to other vasoocclusive disorders, APS shows bland thrombosis of small dermal vessels. APS is distinguished from other noninflammatory vasoocclusive disorders by the presence of elevated antiphospholipid antibody titers [111,113]. Although cutaneous findings are common, they are not among the diagnostic criteria for APS, which require positive antibodies on two occasions at least 6 weeks apart in addition to a history of vascular thrombosis or pregnancy complications [116].

Both treatment and prophylaxis consist of anticoagulation. Some advocate the use of aspirin in those without a history of thrombosis or with superficial venous thrombosis only. Otherwise, long-term warfarin anticoagulation with an internal normalized ratio goal of 3 to 4 is recommended. Immunosuppressive agents and immunotherapy (plasmapheresis, IVIG, cyclophosphamide) may help reduce antibody levels, but these are likely to rebound once treatment is discontinued [111,113]. Rituximab has been shown to be effective for decreasing cutaneous ulcerations and thrombocytopenia; however, it has not been shown to decrease thrombotic events [117].

**Warfarin-Induced Skin Necrosis**

WISN is seen in 0.01% to 0.1% of individuals on warfarin, 3 to 10 days after starting therapy. Women are affected four times more frequently than men, and are most often middle-aged and obese. Three quarters of patients with WISN are being treated for deep venous thrombosis or pulmonary embolism. Atrial fibrillation, valve replacement, and arterial occlusion are disorders in which anticoagulation with warfarin less commonly results in WISN [118].

Although the pathophysiology of WISN is not understood completely, the generally accepted mechanism involves the imbalance between intrinsic procoagulant and antiocoagulant factors created early on during warfarin therapy. Because of their short half-lives, anticoagulant protein C and factor VII are depleted before procoagulant factors II, IX, and X, and this results in an initial hypercoagulability that is thought to trigger onset of WISN [118]. Most individuals on warfarin do not experience this complication, and therefore additional risk factors are likely required to induce necrosis. Protein C and S deficiency, activated protein C resistance, factor V Leiden, antithrombin III deficiency, or prothrombin gene mutations, and heparin-induced thrombocytopenia may be contributory. Protein C deficiency, either inherited or acquired, is a significant risk factor [118], and has been implicated in more than 50% of cases of WISN. High loading doses of warfarin and inadequate overlap
with heparin therapy are also thought to increase risk of early WISN. There are rare reports of cases occurring up to years after the onset of warfarin therapy, and delayed-onset WISN may be related to poor compliance with warfarin, courses of interacting medications, or changing liver synthetic function [118].

Initially, patients experience pressure or pain in the involved area of skin. Poorly demarcated, indurated erythema develops asymmetrically over fatty areas such as the breast, buttock, thighs, and lower abdomen. Induration progresses over 24 to 72 hours to edema with a peau d’orange surface, blue–black discoloration, and hemorrhagic bullae. Localized or widespread full thickness skin necrosis ensues. Histology of involved skin shows noninflammatory thrombosis and fibrin deposition in small dermal vessels with necrosis of the dermis and subcutaneous fat [118]. Differential diagnosis of WISN includes NF, APS, DIC or PF, calciphylaxis, gangrene, embolic disease, cellulitis, and pyoderma gangrenosum. Recent initiation of warfarin should raise suspicion of WISN.

Treatment is discontinuation of warfarin, administration of FFP and vitamin K to reverse its effects, and anticoagulation with heparin. Small lesions may be treated conservatively. Extensive involvement may necessitate debridement, grafting, and in extreme cases, amputation. Deep tissue necrosis, secondary infection, and multiorgan failure are more likely with more widespread disease. Even with treatment, the mortality rate is 15% within 3 months of onset. Prior episodes of WISN are not predictive of future occurrences. In most patients with WISN, future warfarin therapy may be reinstituted with caution, avoiding loading doses and overlapping with heparin initially [118].

Cryoglobulinemia

CG is characterized by precipitation of immunoglobulins from serum in cold temperatures. There are three subtypes. Type I CG constitutes 5% to 25% of cases and presents with monoclonal immunoglobulinemia associated with underlying B-cell lymphoproliferative disorders such as multiple myeloma or Waldenstrom’s macroglobulinemia. Types II and III CG are mixed CGs most often associated with connective tissue disorders, lymphoproliferative disorders, and chronic viral infections. Type I disease is notable for more frequent and severe attacks related to hyperviscosity, and may manifest on the skin as livedo reticularis or Raynaud’s phenomenon. Vascular occlusion rather than immune complex deposition predominates, as these cryoglobulins have a decreased ability to activate the complement cascade. Further cutaneous consequences include digital ischemia and purpura [119].

The mixed CGs are seen in association with infectious and
inflammatory diseases. These underlying conditions are thought to trigger B-cell hyperactivation, which promotes production of cryoglobulins. Meltzer’s triad of palpable purpura, arthralgia, and myalgia may be apparent in 25% to 30% of patients. Other findings include fatigue, neuropathy (70% to 80%), and cutaneous vasculitis. Organ systems other than the skin may be involved as well. The kidneys may be affected in any of the three forms. Bone marrow may be involved in Type I disease, whereas the peripheral nervous system may be affected in Types II and III.

Diagnosis is based on clinical signs and symptoms and elevated serum cryoglobulin levels. Blood samples should be collected in prewarmed vials and maintained at 37°C to prevent precipitation of cryoglobulins. Although involved skin characteristically shows noninflammatory occlusion of dermal vessels by immunoglobulin precipitates, leukocytoclastic vasculitis may be apparent in up to 50% of cases.

Treatment of mild disease is supportive and otherwise focused on any underlying disease process. For more severe disease, options include immunosuppressive agents, plasmapheresis, rituximab plus systemic corticosteroids, and radiation or chemotherapy to treat the associated hematologic malignancy.

CG itself does not typically worsen clinical outcomes of associated conditions. Morbidity and mortality are attributed to associated diseases, and death often results from cardiac disease or infection [120].

**Embolic Diseases**

Embolization of cholesterol or atheromatous material, fat, or tumor may result in striking systemic and cutaneous findings. Cholesterol embolization is typically a result of interventional vascular procedures such as left heart catheterization or angiograms, and can also be associated with cardiac surgery, thrombolysis, and aortic dissection. Less frequently, patients with severe and extensive atherosclerotic disease may experience spontaneous embolization, or emboli triggered by coughing or straining. Showers of cholesterol and atherosclerotic material travel distally and lodge in small arteries of the CNS, lungs, GI tract, kidneys, and skin. Presenting signs and symptoms of embolic disease include mental status changes, pulmonary edema, heme-positive stools, and acute renal failure. Cutaneous findings are striking when apparent and include livedo reticularis, a coarse netlike pattern of violaceous erythema evident on the lower extremities and abdomen (Fig. 70.7). The erythema may be more prominent when the patient is standing compared to the supine position. Tender blue discoloration, petechiae, ecchymosis, ulceration, and gangrene of the feet and toes may eventuate. Pedal pulses are generally intact but bruits may be audible over the femoral artery and
abdominal aorta. Calf tenderness is variable. Similar findings on the arm and hands may result from aortic embolization to the upper extremities [121–123].

**Figure 70.7** Cholesterol emboli. Purpuric plaques involving the toes represent areas of necrosis. Note the livedoid (reticulated) pattern on the sole of the foot, an earlier sign of vascular occlusion.

Fat embolization, seen most commonly after fractures of the long bones or following surgical procedures, is a less common source of embolic disease that presents with the classic triad of pulmonary, neurologic, and cutaneous symptoms. It has rarely been reported following liposuction. Petechiae distributed on the upper body (head, neck, chest, and subconjunctiva) are thought to be pathognomonic and are seen about 50% of the time [124]. Emboli from atrial myxoma, a benign cardiac hamartoma, may result in cyanosis, ecchymosis, splinter hemorrhages, and tender violaceous lesions of the digits [125]. There is no specific laboratory test to confirm cholesterol embolization. Biopsy of the area in question is the only means to confirm the diagnosis [126].

The diagnosis of emboli should be highly suspected in any patient with characteristic skin findings, acute onset end-organ failure, and a recent invasive vascular procedure. Biopsy of the affected organ will show occlusion of vessels with needle-shaped clefts representing cholesterol crystals. Skin is the most accessible and easiest tissue to sample. Atrial
myxoma is evident on echocardiogram, and sampling of affected skin will demonstrate the embolized myxomatous material. Laboratory parameters such as blood urea nitrogen, creatinine, CBC and erythrocyte sedimentation rate, presence of hematuria, and heme-positive stools will be reflective of the organs involved. Treatments include surgical removal or bypass of emboli, amputation of gangrenous digits, and anticoagulation if disease is not thrombolytic-induced [122,125].

Calciphylaxis

Calciphylaxis, or calcific uremic arteriolopathy, is a rare but serious disorder involving calcification of cutaneous arteries and resultant tissue necrosis, usually in the setting of end-stage renal disease (ESRD) and dialysis. Other risk factors include hyperparathyroidism, obesity, white race, female sex, liver disease, malignancy, hypercoagulability, and use of corticosteroids or vitamin D [127]. An elevated calcium phosphate product is not a prerequisite for calciphylaxis, nor is there a correlation between the degree of elevation of calcium, phosphate, or parathyroid hormone levels and the likelihood of developing calciphylaxis. Among patients with ESRD, 1% to 4% develop this disorder.

Calciphylaxis presents with intensely painful indurated erythematous papules, plaques and subcutaneous nodules that may develop a livedoid pattern. Purpura and skin necrosis may evolve within the background of livedo reticularis. A distal, proximal, or mixed distribution may occur, with distal lesions on the lower legs being most common. Proximal presentations involve the upper thighs, buttocks, and lower abdomen, and are associated with a worse prognosis [128,129]. Lesions may even occur on the digits. The differential diagnosis of calciphylaxis includes vasculitis, warfarin necrosis, atheroemboli, CG, APS, protein C or S deficiency, polyarteritis nodosa, and DIC. A deep incisional skin biopsy is usually diagnostic. Calcification is seen primarily in the medial layer of arterioles in the subcutaneous fat, associated with endovascular fibrosis, thrombosis, and necrosis of the subcutaneous fat and overlying skin. Vasculitis is not seen. Laboratory studies addressing causes of hypercoagulability can be helpful as can plain radiographs or technetium 99 bone scans showing vascular calcification.

Treatment of calciphylaxis is controversial and no controlled studies have been performed. Treatment should be multidisciplinary with involvement of nephrology, dermatology, wound care, pain control, and nutrition. Most sources recommend normalization of calcium and phosphorus levels using diet, binding agents, low-calcium dialysis, and cinacalcet or parathyroidectomy if hyperparathyroidism is present [130]. Good wound care and pain control are important. Precipitating factors such as intravenous infusions, oral calcium supplements, or
corticosteroids should be avoided or discontinued. Recent studies show that treatment with IV sodium thiosulfate may improve calciphylaxis outcomes [131]. IV sodium thiosulfate has been effective in cases of both uremic and nonuremic calciphylaxis. Intraleisional sodium thiosulfate can aid in the resolution of cutaneous lesions [130,132]. Although the mortality of calciphylaxis is still high at 60% to 80%, it may be changing with more successful therapies [133].
Systemic Lupus Erythematosus

Lupus erythematosus may involve the skin in many forms. Patients with the acute form of cutaneous lupus erythematosus are most likely to have systemic disease, which may be encountered in an ICU setting. Approximately 80% of patients with SLE have cutaneous manifestations that, although they appear in a multitude of ways, are helpful for identifying affected patients. In fact, 4 of the 11 American Rheumatism Association criteria for diagnosing SLE are cutaneous findings (malar rash, photosensitivity, discoid rash, and oral ulceration). The most characteristic eruption is transient facial erythema involving the malar area and the bridge of the nose that follows sun exposure (Fig. 70.8). The redness, which may be accompanied by edema, lasts between hours and several weeks before resolving without scarring. This “butterfly” rash may be an indicator of internal disease as it may be associated with anti-dsDNA antibody and lupus nephritis [134]. Classically, there is sparing of the nasolabial folds.
Erythema and poikiloderma (hyperpigmentation, hypopigmentation, telangiectasia, and atrophy) also occur over other sun-exposed surfaces such as the V neck area of the chest and the back. On the hands, erythema characteristically spares the knuckles. Tense bullae, also triggered or worsened by sun exposure, may appear in a similar distribution. Mucous membrane lesions occur in 20% to 30% of patients with SLE. Petechiae or shallow ulcerations may be noted on the hard palate and may accompany malar erythema. Gingival, nasal, and vaginal ulcerations may also be seen.
Scalp hair shedding occurs diffusely and is not associated with scarring. Fragile hairs on the periphery of the scalp break and appear short. Hair shedding may also result from telogen effluvium associated with chronic illness. Patients with SLE are also more likely to have alopecia areata [134], which typically manifests as oval patches of scalp alopecia.

Vascular lesions, although not specific to SLE, occur in 50% of patients and are highly suggestive of connective tissue disease. The presence of Raynaud’s phenomenon, periungual telangiectasias, purplish plaques over the tips of fingers and toes with cold exposure, and persistent erythema over the palms, soles, elbows, knees, or buttocks should prompt a search for systemic disease. Vasculitis involving postcapillary venules in the skin manifests as palpable purpura or hemorrhagic wheals. Nodules that ulcerate along the course of arteries reflect deeper, larger vessel involvement. Vascular thrombosis as a consequence of an associated APS causes punched-out ulcers that typically appear over malleolar and pretibial surfaces. The presence of livedo reticularis, thrombosis, and cutaneous infarction also warrants consideration of a prothrombotic state.

Less common cutaneous findings in SLE include a symmetric eruption of erythematous papules on the extremities, which demonstrate palisaded granulomatous inflammation with or without vasculitis on light microscopy. Calcinosis cutis, rarely present in SLE, presents as reddish or violaceous firm plaques or nodules on the head, trunk, or extremities.

Other connective tissue diseases should be considered in the differential diagnosis of the acute lupus syndrome. Eruptions of lupus localized to the head and neck may be difficult to differentiate from rosacea, dermatomyositis, drug-induced photosensitivity, and sunburn. Drug eruptions or exanthems appear similar when lupus manifests diffusely on the skin.

Strict sun protection along with topical corticosteroids and calcineurin inhibitors are the mainstay of treatment for cutaneous lupus. Antimalarial agents with or without corticosteroids or steroid-sparing immunosuppressants may be required for systemic or severe skin disease [135].

Dermatomyositis

Dermatomyositis is a rare disease characterized by a proximal muscle myositis with skin changes. It has a bimodal age distribution and is more common in female and black patients. Initial cutaneous manifestations include swelling of the face and eyelids with a characteristic violaceous erythema (heliotrope rash). These changes become more widespread with
erythema and telangiectasia spreading to the neck, sun-exposed area of
the chest and back in a shawl distribution, as well as to the scalp, elbows,
and knees. These eruptions are usually photosensitive, and pruritus or
burning is a common complaint. Gottron’s sign, which consists of scaly
reddish papules over the knuckle, is considered pathognomonic of
dermatomyositis. Hands may take on the appearance of mechanics’
hands with hyperpigmentation, scaling, fissuring of the fingertips, ragged
cuticles, and enlarged proximal nail fold capillaries. Intermittent malaise,
anorexia, weight loss, and arthralgias are commonly associated
symptoms. Cutaneous disease usually precedes myositis by months.
Dermatomyositis may be drug-induced, with hydroxyurea being the most
common culprit [136].

Aggressive treatment at an early stage allows for better disease control
with lower immunosuppression. Early treatment also reduces the
development of disfiguring calcium deposition in the skin and muscle.
Initial treatment of skin disease includes sunscreens with topical
corticosteroids or calcineurin inhibitors, but resistant skin disease may
require methotrexate or antimalarials. With evident myositis, therapy
requires the use of prednisone (0.5 to 1.5 mg/kg/d tapered slowly over 1
to 2 years) and the addition of a steroid-sparing immunosuppressive such
as azathioprine or methotrexate. It is important to also consider the
coeexistence of other connective tissue diseases such as scleroderma, SLE,
and rheumatoid arthritis in a patient with dermatomyositis. With
appropriate and timely therapy, patients may become disease-free and off
therapy within 2 to 4 years. Of note, patients should be surveyed for an
occult visceral malignancy which is associated with dermatomyositis in
up to 25% of adult cases. Poor prognostic factors include malignancy,
older age, initiating therapy after 24 months of muscle weakness,
extensive cutaneous lesions, dysphagia, and cardiac or pulmonary disease
[137]. The Cutaneous Dermatomyositis Disease and Severity Index
(CDASI) was developed to give an objective basis for disease severity and
to judge clinical response to treatment [138]. A discussion of myositis and
systemic disease associated with dermatomyositis is detailed in Chapter
66.
DERMATOLOGIC ISSUES RELATED TO BONE MARROW TRANSPLANTATION

Graft-Versus-Host Disease

GVHD continues to be a major cause of morbidity and mortality and the major cause of late non-relapse death in hematopoietic cell transplant recipients [139]. Although it is typically a complication of bone marrow and hematopoietic stem cell transplantations, GVHD may also occur in the setting of unirradiated blood product infusion and solid organ transplantation containing lymphoid tissue [140]. Risk factors for GVHD include unrelated donor, HLA mismatch, older age of recipient, female donor with a male recipient, and suboptimal dosing of immunosuppressive drugs. Patients who develop GVHD appear to be at a reduced risk of recurrence of their malignancy, probably due to graft-versus-leukemia or graft-versus-malignancy reactions. GVHD can occur when immunologically competent donor T cells are transferred to a host that is incapable of rejecting them. The pathogenesis is incompletely understood, but the current model suggests a three-phase process. First, recipient tissue damage from conditioning regimens leads to inflammatory cytokines, this activates donor lymphocytes, and finally, alloreactive T cells expand into cytotoxic T cells [139].

GVHD can be divided into acute and chronic forms, with the acute form developing within the first 100 days after transplantation and the chronic form developing after about day 100. Acute GVHD can further classified into classic acute and persistent, recurrent or late acute where an acute presentation develops after day 100. Similarly, chronic GVHD can be classified as classic or overlap, the latter has features of both acute and chronic GVHD [139]. Hyperacute GVHD occurs within 14 days of transplantation [141].

Acute GVHD

The incidence of acute GVHD varies between 20% and 70%, and this range is lower with HLA-matched siblings. Acute GVHD is classified into four grades based on the extent of skin involvement, serum bilirubin level, and the volume of diarrhea per 24-hour period. Skin findings begin...
with painful or pruritic erythematous macules which can arise on the palms, soles, and ears, and evolve into a diffuse morbilliform eruption which is often folliculocentric. In severe cases, there may be progression with bullae formation, erythroderma, and skin necrosis. There have been rare reports of acquired ichthyosis as a manifestation of acute GVHD [142]. The differential diagnosis of acute GVHD includes drug eruptions, viral exanthems, and the eruption of lymphocyte recovery. To further complicate the picture, viral reactivation is a common complication of acute GVHD. Common viruses include HHV6, VZV, parvovirus B19, CMV and Epstein–Barr virus, and specific virus may be more likely to reactivate at different times posttransplantation [143]. Mucous membrane lesions may be difficult to distinguish from mucositis caused by chemotherapy. Histopathology of involved skin classically shows an interface dermatitis and apoptotic keratinocytes. However, the utility of a skin biopsy for diagnosing GVHD is controversial. In a small case series, the presence of eosinophils in biopsy specimens was not a reliable marker favoring drug hypersensitivity reaction over GVHD [144]. In three bone marrow transplant recipients with acute skin eruptions, biopsy led to an initial diagnosis of drug eruption, and immunosuppressive therapy was delayed until additional features of GVHD appeared, resulting in considerable morbidity and two deaths. If there is strong clinical suspicion of GVHD, biopsy findings should not delay or preclude treatment.

**Chronic GVHD**

Chronic GVHD is observed in 33% of HLA-identical sibling transplantations, in 49% of HLA-identical related transplantations, and in 64% of matched unrelated donor transplantations [140]. The model for the pathophysiology of chronic GVHD is autoimmune, and patients with chronic GVHD have a high incidence of antibodies. Lichenoid and sclerodermoid GVHD are the two major forms chronic cutaneous GVHD; however, increasingly variable cutaneous presentations have been reported [139].

The lichenoid variant is characterized by erythematous and violaceous papules and plaques, often distributed on flexural surfaces that resemble lichen planus. The sclerodermoid form presents with sclerotic, indurated white to yellow plaques that involve the dermis. The process may extend to fascia and result in significant tightening of skin and joint contractures. Chronic GVHD most commonly affects the skin but can also affect the oral mucosa, liver, eye, gastrointestinal tract, lungs, esophagus, genitalia, and joints. The oral mucosa is often involved and may demonstrate redness and atrophy of mucosal surfaces, lacy white reticulations of buccal mucosa, and ulcerations. Xerostomia is frequently
present as well.
COMMON DERMATOLOGIC CONDITIONS COEXISTING IN ICU PATIENTS

Abscess

A cutaneous abscess is a painful, fluctuant, walled-off collection of pus found within the skin. A furuncle represents an abscess associated with a hair follicle and a carbuncle is a collection of multiple furuncles. Abscesses and furuncles are typically caused by *S. aureus*, though bacteria can vary by anatomic location. Patients may carry *S. aureus* in their nares or have staphylococcal folliculitis as preceding conditions. The clinical presentation consists of a small red papule that evolves into a tender, erythematous deep-seated nodule that may become fluctuant. The surrounding area may be warm to the touch if there is an associated cellulitis. The differential diagnosis includes an inflamed epidermal inclusion cyst, hidradenitis suppurativa, and arthropod bite. Conservative treatment consists of application of warm compresses. Incision and drainage alone is recommended for smaller abscesses (<5 cm), whereas addition of antibiotics with empiric MRSA coverage is recommended for recurrent abscesses or in patients with positive systemic inflammatory response syndrome (SIRS) criteria [46,145]. Performing a culture is recommended to help guide antibiotic choice.

Folliculitis

Folliculitis is a common disorder characterized by inflammation of hair follicles. Infectious folliculitis is usually caused by staphylococci, *Pseudomonas*, or *Malassezia furfur*, whereas noninfectious folliculitis is the result of trauma to or occlusion of the pilosebaceous unit. Herpes virus and dermatophytes are less commonly implicated. Folliculitis presents as papules or pustules on an erythematous base with a centrally extruding hair. The lesions may be pruritic and are most often found on the face, scalp, thighs, axillae, and inguinal area. Pseudomonal folliculitis may be more inflammatory and localized to a distribution that would be covered by a bathing suit. Pityrosporum folliculitis may be localized to the upper back and chest and be extremely pruritic [146]. Diagnostic tools include a potassium hydroxide (KOH) preparation, Gram stain, and bacterial, fungal, and viral cultures. Treatment is directed at the underlying etiology. Most cases will respond to appropriate topical and/or oral antibiotics (most commonly anti-staphylococcal). Pityrosporum folliculitis requires topical or oral antifungals and
pseudomonal folliculitis is often self-limited, but may require fluoroquinolones in immunosuppressed patients. The prognosis is generally good, but some patients experience recurrent disease [147].

Peripheral Edema

Peripheral edema, which is commonly seen among elderly and hospitalized patients, occurs when capillary hydrostatic pressure and filtration exceeds the lymphatic drainage rate. Common causes of edema include heart failure, renal failure, nephrotic syndrome, cirrhosis, venous thrombosis, or medications, particularly calcium channel blockers. Acute exacerbations of chronic edema may cause edema blisters which present as asymptomatic, noninflammatory tense vesicles and bullae with clear fluid, usually on the distal lower extremities. Edema blisters can be distinguished from other blistering disorders by clinical history and physical examination. If needed, a biopsy for routine histopathology and immunofluorescence may help exclude other blistering disorders. Acute peripheral edema may also produce local dermal edema, leading to induration of the skin and dimpling, known as peau d’orange.

Stasis Dermatitis

Stasis dermatitis occurs in the setting of venous hypertension due to valvular incompetence. Risk factors include conditions that exacerbate lower extremity edema such as obesity, congestive heart failure, cirrhotic liver disease, and chronic renal insufficiency. Typically, there is reddish mottling and a yellowish or brown discoloration of the medial lower legs, corresponding to the location of major communicating veins. There may be an eczematous component as well that often results from contact sensitization to topical medicaments applied to the legs. There are often other signs of venous hypertension, including edema, varicose veins, and venous leg ulcers. Over years, the legs may develop lipodermatosclerosis, which occurs when adipose tissue becomes indurated and adherent to fascia, and lower legs take on the appearance of an inverted wine bottle. The diagnosis is evident in the right clinical context. However, astute eczema, contact dermatitis, and cellulitis may also be considered in the differential. Of note, bilateral cellulitis of the legs is extremely rare and is often confused with stasis dermatitis. Careful clinical evaluation can lead to the correct diagnosis [148].

Relief of itching is attained through the regular application of emollients and the use of class IV or V topical steroids. Long-term
management involves improving venous return through various measures such as leg elevation, elastic compression, and exercises to strengthen calf muscles. Care should be taken to avoid trauma to the leg that would facilitate ulcer formation. In severe cases, ligation of incompetent communicating veins may be necessary. Secondary infection is not uncommon as the barrier function of the skin is lost with chronic stasis dermatitis. The presence of bacteria must be recognized as a secondary event to the stasis, and treatment with antibiotics in conjunction with topical steroids is routine.

**Pressure Ulcers**

Pressure ulcers are areas of ischemic soft tissue necrosis resulting from prolonged pressure, shearing force, or friction anywhere on the body. Sites that are most frequently involved include skin overlying bony prominences of the sacrum, ischial tuberosities, heels, greater trochanters, and lateral malleoli.

Nonblanching erythema of skin overlying a bony prominence may signify impending ulceration. Other early indicators include warmth, edema, or induration of skin. Initial ulcers appear punched out. Ulceration may occur as partial thickness skin loss, full thickness skin loss involving subcutaneous tissue, or full thickness skin loss extending to muscle, tendon, or bone. Associated pain may be severe and should be managed aggressively. Treatment involves relief of pressure, which may be accomplished through frequent position changes and supportive surfaces such as air, liquid, or foam cushions. Local wound care includes cleansing with normal saline, debridement, and occlusive hydrocolloid dressings or foam dressings to optimize healing [149]. Nutritional supplementation should be considered for malnourished patients. A recent randomized control trial showed improved pressure ulcer healing in malnourished patients given a nutritional formula enriched with arginine, zinc, and antioxidants [150]. The majority of pressure ulcers are superficial and heal by secondary intention, but operative repair is necessary for some cases. Electrical stimulation can be used as an adjunctive therapy [149]. Wounds should be monitored for local infection and treated accordingly. Sepsis and osteomyelitis may further complicate ulceration and lead to mortality.

**Psoriasis**

In its most common form (chronic plaque psoriasis), psoriasis presents as chronic well-demarcated erythematous plaques with adherent silvery scale, most commonly over the elbows, knees, and scalp. In guttate (raindrop-like) psoriasis, there are smaller psoriatic papules and plaques diffusely over the body, and this is often triggered by streptococcal
infections. Sudden onset of sterile pustules that coalesce to form “lakes of pus” at the edges of psoriatic plaques associated with fever typifies the more generalized form of pustular psoriasis (Fig. 70.9). Pustular psoriasis is not infectious in etiology. Hypocalcemia and pregnancy may be triggering factors in pustular psoriasis. In erythrodermic psoriasis, there is bright red erythema involving ≥90% of the skin. These patients are itchy and also complain of chills from the extensive heat loss due to dilatation of cutaneous vessels. In both pustular and erythrodermic forms, patients are generally toxic and may have associated ARDS, congestive heart failure, pneumonia, or viral hepatitis (see “Exfoliative Erythroderma” section). There is a recognized association of psoriasis, particularly severe disease, with increased risk of cardiovascular, cerebrovascular, and peripheral vascular disease [151,152].
First-line treatment of mild cases is with topical corticosteroids and the vitamin D derivative, calcipotriene, whereas more severe cases require ultraviolet phototherapy, methotrexate, systemic retinoids, or biologic agents. For erythrodermic psoriasis, cyclosporine and infliximab appear to be the fastest acting agents; however, their use is predicated on severity of presentation and patient comorbidities [153].

**Atopic Dermatitis**

Atopic dermatitis is characterized by eczematous skin changes and typically involves flexor surfaces in adults, although any body area may be involved. The disease is most common among young children in whom the tendency for atopic dermatitis is to gradually improve with age; however, in a minority of patients, disease persists into or manifests in adulthood. Affected individuals frequently have a personal or family history of seasonal allergies and asthma. In the most severe cases, eczematous dermatitis may evolve into erythroderma (see “Exfoliative Erythroderma” section). Other complications of this disease include secondary bacterial infection (impetigo) or herpetic infection, a condition known as eczema herpeticum. Treatment of atopic dermatitis includes topical corticosteroids, emollients, oral antihistamines, antibiotics as needed, and management of coexisting asthma and allergies.

**Contact Dermatitis**

Contact dermatitis occurs when direct contact with a substance triggers an inflammatory response in the skin. Irritant contact dermatitis, which accounts for 80% of contact cases, occurs when a chemical directly induces damage to the skin. Common irritants include soap, water, and solvents. Allergic contact dermatitis makes up the remaining 20% of cases, and is an immunologically mediated, delayed (Type IV) hypersensitivity reaction. Causes of allergic contact dermatitis in hospitalized patients include adhesives, topical medications, topical antibiotics, preservatives, fragrances, metals, and rubber components. Older adults have an impaired epidermal barrier and are more susceptible to both irritants and allergens. Patients with stasis dermatitis and lower extremity ulcerations are at increased risk of allergic contact
dermatitis [154]. Acute contact dermatitis, whether irritant or allergic in nature, presents with pruritic papules and weepy vesicles on an erythematous base, initially localized to the area of contact. Chronic lesions are erythematous plaques of thickened skin with accentuated skin markings, scale, and occasionally fissuring. The differential diagnosis may vary depending on the location of the eruption, but generally includes atopic dermatitis, seborrheic dermatitis, stasis dermatitis, and tinea. Rarely, systemic contact dermatitis can occur when a sensitized individual is exposed to a cross-reacting substance. This presents with erythema of the buttocks and flexural skin folds. The most common allergens implicated in systemic allergic contact dermatitis are nickel, aminoglycoside antibiotics, corticosteroids, balsam of Peru, and plants [155]. Because contact dermatitis causes a break in the epidermal barrier, secondary infection is common. A common mistake is to attribute the dermatitis to the infection rather than seeing the infection as the result of the dermatitis. History and physical examination are usually sufficient to make the diagnosis. Patch testing may be useful in identifying potentially relevant contact allergens. Treatment involves avoidance of the offending agents. For mild to moderate cases, topical steroids and bland emollients are used. For extensive and severe cases, a 2- to 3-week tapering course of oral prednisone, along with an oral antihistamine to relieve pruritus, is appropriate. For lesions that are oozing and crusting, wet-to-dry or aluminum acetate compresses may be helpful. Treatment of any secondary infection speeds resolution. It is not uncommon to treat patients with both steroids and antibiotics to treat both the cause and the secondary infection.

Seborrheic Dermatitis

Seborrheic dermatitis is a common, usually asymptomatic, scaly eruption of the oil gland–bearing skin of the scalp, face, and trunk. It may present in mild cases as common dandruff and in severe cases as a florid erythematous scaling eruption involving the scalp, eyebrows, eyelids, paranasal folds, chest, and axillae. Seborrheic dermatitis typically occurs in healthy individuals, but is usually most severe among immunocompromised patients and among patients with neuropsychiatric disorders. An acute severe presentation should prompt testing for HIV. Paradoxically, acute severe seborrheic dermatitis is also common following initiation of HAART among patients with baseline low CD4 counts [156]. Malassezia yeasts are frequently seen in high levels on the skin of patients with seborrheic dermatitis, but their pathogenic role is unclear. Nonetheless, treatment with antifungals is effective. Diagnosis of seborrheic dermatitis is clinical. The differential diagnosis includes
psoriasis, tinea capitis, rosacea, and atopic or contact dermatitis. Treatment is with antidandruff shampoos containing selenium sulfide, zinc pyrithione, ketoconazole, or ciclopirox and topical antifungals (ketoconazole cream, etc.) or mild corticosteroids (hydrocortisone cream) [157]. If the patient is not bothered by this rash, it need not be treated.

**Transient Acantholytic Dermatosis (Grover’s Disease)**

Transient acantholytic dermatosis (TAD) is a common eruption consisting of discrete variably pruritic red to brown nonfollicular scaly keratotic papules of the upper trunk seen typically in middle-aged white men, more often in the wintertime. TAD is often seen in bedbound patients and can be associated with malignancies. Like miliaria, TAD is often associated with heat and excessive sweating; however, its histopathology, clinical appearance, and treatment are different. Lesions of TAD are more keratotic and scaly than those of miliaria, and histopathology reveals epidermal acantholysis rather than spongiosis. TAD may also be confused with folliculitis, which consists of follicular non-scaly papules and pustules. Treatment of TAD consists of mitigation of heat and sweating, application of mid-strength topical corticosteroids (such as triamcinolone cream 0.1% twice daily for up to 2 weeks), topical lotions containing pramoxine or menthol, and oral antihistamines (such as hydroxyzine 10 to 25 mg every 6 hours as needed for itch). In severe cases, oral retinoids such as isotretinoin (0.5 to 1 mg per kg daily) may be used. The condition usually remits slowly over weeks to months but can recur.

**Miliaria**

Miliaria is a common skin eruption among hospitalized patients. It is caused by blockage of eccrine sweat ducts that occurs in the setting of fever and excessive sweating, often in patients who are largely confined to bed. It occurs in three main forms: miliaria crystallina, which presents as tiny clear asymptomatic superficial vesicles on the trunk, head, and neck; miliaria rubra, which presents as uniform, small pruritic erythematous papules on the trunk, neck, and flexural extremities (Fig. 70.10); and miliaria profunda, which presents as firm, flesh-colored symptomatic nonfollicular papules or pustules on the trunk and extremities of patients who have had repeated episodes of miliaria rubra. It is important to be able to recognize miliaria to distinguish it from more medically significant entities such as disseminated herpes simplex, varicella, or candidiasis. The distribution of miliaria in areas where the skin is occluded and where excessive sweating occurs is helpful for the diagnosis.
Miliaria crystalline does not need to be treated, as it is self-limited and asymptomatic. Miliaria rubra may be treated by decreasing the heat and humidity of the patient’s environment. Some reports state that oral ascorbic acid and topical lanolin can be helpful, but no controlled trials have been done [158].

**Tinea Corporis**

Fungal infection is named for the affected body part. Tinea corporis is the common, superficial fungal infection found on any area of the skin excluding the palms, soles, scalp, and groin. *Trichophyton rubrum* is the most common causative organism, although any dermatophyte may be responsible. Tinea corporis presents as one or multiple annular lesions with erythematous scaly borders that exhibit centrifugal spread and leave a central clearing. Other clinical presentations include tinea profunda, which exhibits a granulomatous or verrucous appearance due to an excessive host inflammatory response, and Majocchi’s granuloma, which presents as follicular-based pustules or papules. The differential diagnosis includes nummular eczema, subacute cutaneous lupus erythematosus, and granuloma annulare. The diagnosis is easily confirmed by potassium hydroxide (KOH) examination of scale or fungal culture. Limited disease may be treated with topical agents such as
naftifine 1% cream, terbinafine 1% cream, or clotrimazole 1% cream applied twice daily for 2 to 4 weeks in combination with a topical steroid if there is significant local inflammation [159]. More extensive or recalcitrant disease may require systemic treatment such as itraconazole 100 mg daily or terbinafine 250 mg daily for 2 weeks. Prognosis is excellent with 70% to 100% cure after treatment, but recurrence is common [160], especially among the immunosuppressed.

**Scabies**

Scabies is a common, extremely pruritic dermatosis caused by infestation with the mite, *Sarcoptes scabiei*. It spreads from person to person through direct skin contact, although it can rarely spread through fomites such as bedding or towels. Scabies should be considered in the differential diagnosis of any patient with severe generalized itching, especially if they have had contact with residential institutions such as nursing homes, where it may be endemic.

Patients with scabies present with severe generalized pruritus, sparing the head and neck, which is worse at night. The pathognomonic lesions are linear burrows (Fig. 70.11), most often found on the hands and feet, especially in the web spaces. Papules, pustules, vesicles, and nodules may also occur, the last being especially common in children. Scabies has a predilection for the hands, feet, wrists, axillae, abdomen, buttocks, and genitalia. Immunocompromised and neurologically impaired patients may present with the crusted or “Norwegian” variant of scabies, in which the skin is markedly thickened and crusted. These crusts are filled with thousands of mites and the patients are highly infectious.
Definitive diagnosis of scabies is made by observing skin scrapings microscopically for mites, eggs, or mite feces. First-line treatment of scabies is with topical 5% permethrin cream applied from neck down and left on overnight, with special attention to the genitalia, web spaces, and under the fingernails. All household members or suspected contacts over the age of 2 months and nonpregnant individuals should be treated simultaneously. All bedding, clothing, and towels are then laundered. The application is repeated after 1 week. When topical treatment is impractical, oral ivermectin may be given as a single dose of 200 µg per kg of body weight, repeated in 1 week. Itching can persist for up to a month after adequate treatment. Patients can be concurrently treated with topical corticosteroids and oral antihistamines to help alleviate itch [161].

INFECTION DISEASE PROBLEMS IN THE INTENSIVE CARE UNIT
ROBERT W. FINBERG
Approach to Fever in the ICU Patient

RAUL E. DAVARO • RICHARD H. GLEW

Humanity has but three great enemies: fever, famine and war; of these by far the greatest, by far the most terrible, is fever [1].

Sir William Osler

APPROACH TO THE FEBRILE PATIENT

Fever is a common symptom among hospitalized patients and one-third of all medical patients develop fever [2]. The incidence of fever in the intensive care unit (ICU) ranges from 25% to 70% [3]. In addition to being common, fever has also been shown to be independently associated with mortality for patients admitted to the ICU.

Pathophysiology

As homeothermic organisms, humans must regulate their temperature to maintain fundamental biologic processes [2]. Core temperature typically exhibits diurnal rhythmicity, with a nadir of about 36.2°C in the morning and a peak of approximately 37.7°C in the afternoon [4]. Temperature elevates to >39°C in febrile response to infection or other stress [4].

Fever is the result of an upward adjustment in the thermoregulatory set point involving cytokine-mediated rise in core temperature, generation of acute-phase reactants, and activation of numerous physiologic, endocrinologic, and immunologic systems [5]. In contrast, simple heat illness or malignant hyperthermia is an unregulated rise in body temperature caused by inability to eliminate heat adequately [4]. Physiologically, fever begins with the production of one or more
proinflammatory cytokines in response to exogenous pyrogenic substances (such as microorganisms and toxic agents) or immunologic mediators. Interleukin-1 (IL-1) was the first purified protein with demonstrated pyrogenic properties; subsequently, other cytokines such as tumor necrosis factor (TNF), lymphotoxin, interferons (IFNs), and interleukin (IL-6) were also documented to induce fever. Cytokines interact with receptors located at the organum vasculosum of the lamina terminalis, causing synthesis and release of prostaglandins, chiefly prostaglandin E2, which raise body temperature by initiating local cAMP production, which resets the thermoregulatory set point of the hypothalamus, and by coordinating other adaptive responses, such as shivering and peripheral vasoconstriction [5]. Fever induces the production of heat shock proteins (HSPs), a class of proteins critical for cellular survival during stress. HSPs that act as molecular chaperones may have an anti-inflammatory role and indirectly decrease the level of proinflammatory cytokines [4].

Measurement

The Society of Critical Care Medicine and the Infectious Disease Society of America issued a consensus statement recommending that core temperature of higher than 38.3°C (101°F) be considered fever [6].

In the ICU, body temperature can be measured using a number of different methods, including thermistors on intravascular, bladder, esophageal, or rectal probes, in addition to infrared tympanic membrane and temporal artery thermometers. Although the pulmonary artery catheter has been considered the gold standard measurement technique, in most situations, relatively small differences exist between the other commonly used methods [7].
ETIOLOGY OF FEVER IN THE INTENSIVE CARE PATIENT

The prevalence of fever in the ICU depends on the population studied and the definition of fever used. The major causes of abnormally elevated temperatures in critically ill patients can be broadly classified as infectious fevers, noninfectious fevers, and hyperthermia syndromes (Table 71.1) [8].

Noninfectious Causes of Fever

About one-half of all fevers in the ICU are caused by noninfectious etiologies (Table 71.1) [2,8,9]. Noninfectious causes of fever are inflammatory conditions that activate the cytokine system and trigger a systemic inflammatory response syndrome (SIRS) a clinical response to inflammation [10]. Conditions associated with fever as one of the components of SIRS can occur in critically ill patients with large hematomas; acute vasculitis; subarachnoid hemorrhage; dissection of an aortic aneurysm; mesenteric ischemia; heat stroke; pancreatitis; or hyperthyroidism [2,8,9]. Fever may appear in the patient in whom the stress of surgery unmasks adrenal insufficiency or following bilateral adrenal hemorrhage in patients with a history of thromboembolic disease, recent surgery, and/or anticoagulant therapy [11]. Fever is a cardinal manifestation of delirium tremens in patients with acute alcohol
withdrawal, although it is necessary to exclude other complications of alcohol abuse such as pneumonia or spontaneous bacterial peritonitis [12]. Likewise, fever associated with seizures must be differentiated from possible underlying causes of seizure, such as meningitis; encephalitis; brain abscess; or stroke.

Drug fever is a disorder characterized by a febrile response coinciding temporally with the administration of a drug in the absence of underlying conditions that can be responsible for the fever. A key feature that differentiates drug fever from fever of other causes is that it disappears once the offending drug is discontinued. Drug fever tends to be a diagnosis of exclusion, often suspected among patients with otherwise unexplained fevers [13].

Neoplastic fevers are now most commonly encountered in the setting of febrile patients with a known malignancy, and present a diagnostic challenge in differentiating whether fever is attributable to infection, therapy, or disease [14].

Hyperthermia is the unregulated rise in body temperature and a failure of the thermoregulatory homeostasis; malignant hyperthermia, neuroleptic malignant syndrome and serotonin syndrome are conditions that produce a high temperature resulting from hypothermia, not fever [15].

Conspicuously absent from Table 71.1 is atelectasis, a process widely regarded as a cause of fever, especially in the postoperative patient where atelectasis is common, although there is no clear evidence of such a connection [16].

Accurate and timely recognition of noninfectious causes of fever can avoid unnecessary use of antibiotics, reducing the risks of untoward reactions.

Infectious Causes of Fever

On any given day, approximately 1 of every 25 in patients in U.S. acute care hospitals has at least one health care–associated infection. Pneumonia and surgical-site infection are the most common infection types, and *C. difficile* is the most common pathogen. Infections other than those associated with central catheters, urinary catheters, and ventilators account for the majority of the U.S. burden of health care–associated infections and may warrant increased attention (Table 71.2) [17].

**Bacteremias**

Secondary bacteremia may originate from multiple sources (e.g., lungs, genitourinary tract, abdomen, skin, and soft tissues) or can develop as a consequence of vascular invasion via intravenous and intra-arterial lines and monitors; temporary transvenous pacemakers; and intra-aortic assist devices [17].

**Health Care–Associated Pneumonia**

Respiratory infections continue to be the most common cause of sepsis and septic shock. Mechanical ventilation with an endotracheal tube increases the risk of pneumonia 6- to 20-fold [2]. Ventilator-associated pneumonia (VAP) is the most common infection acquired in the ICU [17].

**Intra-Abdominal Infections**

Abdominal infections represent the third most common cause of sepsis in the intensive care unit and present an important diagnostic and therapeutic challenge.  
The spectrum of diseases that can lead to ICU admission or complicate an ICU stay ranges from common, community acquired diseases to severe nosocomial infections. Rarely do intra-abdominal infections present as the only reason for admission to the ICU. Patients may have multiple
comorbidities, be at high risk for treatment failure, and may already be septic at the time of admission. Other types of infection classically present during treatment for a different medical problem such as acalculous cholecystitis, or complicated *C. difficile* colitis after the extensive use of broad-spectrum antibiotics, an increasing nosocomial problem of the last few years [17–19].

**Urinary Tract Infections**

Urinary tract infection (UTI) is one of the most common hospital-acquired infections; 70% to 80% of these infections are attributable to an indwelling urethral catheter. Partial or total obstruction or local complications (e.g., intrarenal or perinephric abscesses) must be suspected in patients with bacteremic pyelonephritis if fever and bacteremia persist despite appropriate antibiotic therapy [20].

**Nosocomial Sinusitis**

Nasogastric and nasotracheal tubes; facial fractures; and nasal packing are common predisposing factors to nosocomial sinusitis, an occasional cause of fever in the ICU [21].
DIAGNOSTIC CONSIDERATIONS

In some ICUs, the finding of fever triggers an automatic fever workup, resulting in many tests that are time consuming, costly, and disruptive to the patient and staff. The American College of Critical Care Medicine and the Infectious Disease Society of America convened a task force to provide guidelines for evaluation of new fever in patients older than 18 years in the ICU setting [6].

History and Physical Examination

If able to communicate, the patient should be interviewed to identify localizing complaints. The patient and the patient’s electronic medical record should be reviewed thoroughly for a history of relevant antecedent problems (e.g., previous infections, cancer, allergic reactions to drugs). If the patient is unable to communicate, the medical record and medical personnel can provide insightful information concerning duration of intravascular accesses; amount and purulence of sputum or wound drainage; changes in skin condition; apparent abdominal or musculoskeletal pain or tenderness; difficulty in handling respiratory secretions and feedings; and changes in ventilator support parameters. Relatives and friends of the patient can provide epidemiologic information related to the patient’s exposures and risk factors for infections.

Physical examination of the febrile ICU patient may be difficult to conduct caused by limitations imposed by wound dressings, catheters, ventilator tubes, and monitors, but nonetheless it should be thorough. Skin examination may demonstrate findings suggestive of drug reaction, vasculitis, endocarditis, or soft tissue necrosis. All intravenous and intraarterial line sites should be inspected; a tender intravenous access site, with or without purulence, can indicate septic thrombophlebitis. Spreading erythema, warmth, and tenderness that appear to indicate cellulitis of an extremity also can be the hallmarks of deep venous thrombophlebitis; pyarthrosis; or gout. After the first 24 hours postoperatively, wounds should be examined; this may require fenestrating or changing a cast to allow for examination of a fractured extremity if no other source of fever is found.

Head and neck examination can provide important signs of systemic and localized infection. Fundoscopic examination, preferably by an ophthalmologist, can provide clues to systemic fungal or viral infections in the immunocompromised. Hospital-associated sinusitis often develops in patients who required extensive period of intensive care, especially in
the setting of nasal intubation and may have a paucity of associated symptoms. Oral lesions of recrudescent herpetic stomatitis are common in the ICU setting and often are obscured by the presence of oral endotracheal tubes or orogastric feeding tubes. These lesions may be extensive; more ulcerated and necrotic; and less vesicular in appearance in a seriously ill patient.

Examination of the lungs can be difficult for the intubated ICU patient and often is unrewardingly nonlocalizing and nonspecific. More sensitive (although nonspecific) indicators of pneumonia include chest imaging studies; occurrence of unexplained deterioration in oxygen exchange; and changes of the character of respiratory secretions. Unfortunately, pulmonary infiltrates and hypoxemia are nonspecific signs, because they can be seen with congestive heart failure; atelectasis; aspiration pneumonitis; pulmonary embolism; acute respiratory distress syndrome; and, less commonly, reactions to medications and pulmonary hemorrhage. Cardiac examination may demonstrate a new or changing murmur possibly due to endocarditis.

Abdominal findings can be misleadingly unremarkable in the elderly, in the patient with obtunded sensorium, and in the patient receiving sedatives. Abdominal examination can be confounding in the patient with recent abdominal or thoracic surgery. Abdominal pain and tenderness may be localized (cholecystitis; intra-abdominal abscess; and diverticulitis) or generalized (diffuse peritonitis, ischemic bowel, and antibiotic-associated colitis). Examination of the genitalia and rectum may demonstrate unsuspected epididymitis; prostatitis; prostatic abscess; or perirectal abscess.

**Diagnostic Studies**

Because the information provided by positive blood cultures has important prognostic and therapeutic implications, blood cultures should be obtained for patients with new onset of fever when clinical evaluation suggests an infectious cause. The volume of blood that is obtained for each blood culture request is the most important variable in recovering bacteria and fungi from patients with bloodstream infections. For adults, 20 to 30 mL of blood per culture set is recommended and may require more than two bottles depending on the system [6,22].

Rapid identification of microorganisms growing in blood culture bottles using a new proteomic technology, matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF
MS) is promising [23]. When urinary tract may be the source of fever, a urine specimen (aspirated from the catheter sampling port) should be obtained and evaluated by microscopy, and quantitative culture [6]. For patients with clinical suspicion of pneumonia, chest imaging with radiograph or CT scan is mandatory, and efforts should be made to obtain secretions for stains and cultures. Microscopic examination of pulmonary secretions may provide timely information about possible causative organisms. Results on Gram’s staining and culture of sputum are positive in more than 80% of cases of pneumococcal pneumonia when a good-quality specimen (>10 inflammatory cells per epithelial cell) can be obtained before, or within 6 to 12 hours after, the initiation of antibiotics. The yield diminishes with increasing time after antibiotics have been initiated and with decreasing quality of the sputum sample [24]. Nebulization with hypertonic saline (the so-called induced sputum) may increase the likelihood of obtaining a valid sample. Techniques aimed at obtaining samples of secretions and tissue from the distal respiratory tract include protected and nonprotected bronchoalveolar lavage (BAL); transbronchial biopsy; protected specimen brush and telescoping plugged catheter; video-assisted lung biopsy; and open lung biopsy. Respiratory secretions from these sampling methods may use quantitative culture thresholds to improve the diagnostic accuracy. BAL is the preferred diagnostic approach, with a low rate of complications (2%) and a diagnostic yield between 30% and 90% depending on the type of population studied; prior antibiotic treatment; and the definition of pneumonia used [25].

In general, abnormal fluid collections (pleural effusion, joint effusion, and ascites) should be sampled for microscopic, hematologic, and chemical analysis, as well as microbiologic culture. Microbiologic yield from ascites culture has been shown to be greater when ascitic fluid is placed into blood culture or fungal isolator media [22]. Infection; crystal-induced disease; trauma; and a variety of systemic diseases can create a painful, swollen peripheral joint; arthrocentesis is indicated to establish the nature of the effusion [26]. Nosocomial bacterial meningitis may result from invasive procedures (e.g., craniotomy; placement of internal or external ventricular catheters; lumbar puncture; intrathecal infusions of medications; or spinal anesthesia), complicated head trauma, or in rare cases, metastatic infection in patients with hospital-acquired bacteremia. These cases of meningitis are caused by a different spectrum of microorganisms than cases acquired in the community setting. The diagnostic workup consists of neuroimaging; cerebrospinal fluid analysis (cell counts; Gram’s staining; biochemical tests for glucose and protein; and cultures); and cultures of blood [27].

Computed tomography (CT) scan should be considered as one of the most useful imaging techniques in assessing intra-abdominal infections.
Image quality and information can be optimized by the application of intravenous, oral, or rectal contrast [28].

Stool samples should be sent for determination of *C. difficile* toxin PCR for patients with diarrhea, fever and leukocytosis who received an antibacterial agent, proton pump inhibitor or chemotherapy 60 days before the onset of diarrhea [18].

A novel approach for determining the necessity and optimal duration of antibiotic therapy is the use of biomarkers, such as procalcitonin (PCT) levels, which become upregulated during bacterial infections and appear to mirror the severity of infections. Procalcitonin, the precursor peptide of the hormone calcitonin, is released ubiquitously in response to primarily bacterial toxins and bacteria-specific proinflammatory mediators, particularly interleukin 1b, tumor necrosis factor, and interleukin 6. In previous studies, a strong correlation was observed between the concentration of PCT and the extent and severity of bacterial infections.

PCT levels are routinely used as surrogate marker for bacterial infection to discontinue empiric antibacterial therapy for patients found to have low levels of this marker [29].

Two approaches that have gained particular attention for the diagnosis of invasive fungal infections are detection of 1,3-β-D-glucan (BDG) and galactomannan, major constituents of fungal cell walls, and polymerase chain reaction amplification of fungal DNA [30,31].
TREATMENT CONSIDERATIONS

Initial Antibiotic Therapy

Aggressive resuscitation bundles, adequate source control, appropriate antibiotic therapy, and organ support are cornerstones for the successful treatment of patients with severe sepsis [32]. Thus, intravenous antibiotic therapy should be started as early as possible and should cover all likely pathogens. It has not been determined whether combination antimicrobial therapy produces better outcomes than adequate single-agent antibiotic therapy in patients with severe sepsis. Current guidelines recommend combination antimicrobial therapy only for neutropenic sepsis and sepsis caused by Pseudomonas species. Empirical antifungal therapy should be used only for patients at high risk for invasive candidiasis. Antimicrobial therapy should be evaluated daily to optimize efficacy, prevent resistance, and avoid toxicity. Positive cultures may permit narrowing of the spectrum of antibiotic coverage or may dictate that additional organisms need to be covered by added antimicrobial therapy. Negative cultures of a patient who is unimproved yet stable on broad therapy indicate that antibiotics should be discontinued and the patient reevaluated. Negative cultures in a febrile patient who is unimproved or worsened may be a clue to disseminated fungal infection, and empiric antifungal therapy should be considered [33].

For an ICU patient, one should assume that in addition to the usual expected pathogens at a given site, infection is likely to involve more opportunistic hospital-associated pathogens, such as S. aureus (including methicillin-resistant S. aureus or MRSA) and coagulase-negative staphylococci; and multidrug-resistant enteric gram-negative bacilli and lactose nonfermenting gram-negative bacilli (e.g., Pseudomonas aeruginosa and Acinetobacter species) and yeast (Candida species) [34]. In light of possible impairment of mechanical and immunologic defenses and the presence of intravascular lines, the febrile ICU patient should be considered to be bacteremic until proven otherwise. Patients with intravascular lines and bacteremia should have their lines removed, if possible [35].

Once the spectrum of potential infecting organisms has been narrowed to one or a few likely candidates, empiric antibiotic therapy should be changed according to generally accepted principles as outlined later in the chapter (Table 71.3) [36].

Dosage and Route of Administration

A vast array of pathophysiologic changes can occur in critically ill patients that can complicate antibiotic dosing. As a rule, the intravenous route is preferred because of possible unreliable absorption from muscle and the gastrointestinal tract caused by impaired hemodynamics and/or gastrointestinal function [37].

Hydrophilic antibiotics (e.g., aminoglycosides, \(\beta\)-lactams, glycopeptides, and colistin) are mostly affected with the pathophysiologic changes observed among critically ill patients with increased volumes of distribution and altered drug clearance (related to changes in creatinine clearance). Lipophilic antibiotics (e.g., fluoroquinolones, macrolides, tigecycline, and lincosamides) have lesser volume of distribution alterations, but may develop altered drug clearances. Augmented renal clearance (ARC) refers to the enhanced renal elimination of circulating solute (such as waste products and drugs). This is based in part on PK studies demonstrating elevated renal clearances of \(\beta\)-lactams, aminoglycosides, and glycopeptides among subsets of critically ill patients.

Dosing intervals for most antibiotics are selected so that the drugs are administered every three to four serum half-lives (\(t_{1/2}\)). Because most of the older parenterally administered \(\beta\)-lactam antibiotics have a \(t_{1/2}\) of about 1 hour, intravenous penicillins and cephalosporins traditionally are given every 4 hours. However, the \(t_{1/2}\) for cefazolin, cefotaxime, and ceftazidime is 1.5 to 2.5 hours, and these agents can be administered less frequently, perhaps every 6 to 8 hours, even for serious infections; for ceftriaxone, the \(t_{1/2}\) is 8 hours and the administration frequency is every 12 to 24 hours. In the clinical setting, \(\beta\)-lactam optimization strategies often include the use of a prolonged infusion (i.e., same dose administered over 3 to 4 hours) for each dosing interval or as a
continuous infusion where the total daily dose is given at a constant rate over 24 hours. Each of these strategies has been reported to enhance the efficacy when compared to conventional regimens. Levofloxacin and the macrolide azithromycin are administered once a day (Table 71.2) [38,39].

**Antimicrobial Therapy**

Antimicrobial administration within the first hour of documented hypotension is associated with increased survival in adult patients with septic shock, and it should be initiated at maximal recommended doses for all patients with suspected life-threatening infections without delay [32].

**Initial Therapy of a Life-Threatening Infection**

A variety of studies including infected and septic patients show that inappropriate antimicrobial therapy is a consistent predictor of poor outcomes [6,40]. The choice of empirical therapy depends on the suspected site of infection and local microbial-susceptibility patterns. Inappropriate or delayed antibiotic treatment is associated with increased mortality. Thus, intravenous antibiotic therapy should be started as early as possible and should cover all likely pathogens. For example, suspected acute overwhelming infection of unknown or uncertain source of an ICU patient warrants therapy with vancomycin to cover *S. aureus*, including MRSA, plus a third-generation or fourth-generation cephalosporin or a fluoroquinolone to treat gram-negative bacilli. If hospital-acquired, ventilator-associated, or health care–associated pneumonia is likely, a fluoroquinolone such as levofloxacin or gatifloxacin along with piperacillin–tazobactam and vancomycin provides optimal coverage for gram-negative enteric bacilli; atypical bacterial pathogens, such as *Legionella*, *Chlamydia trachomatis*, and *Mycoplasma*; and MRSA [25,41]. In patients with febrile neutropenia, an antipseudomonal penicillin (piperacillin/tazobactam) or cephalosporin (ceftazidime or cefepime) or carbapenem (meropenem or imipenem) is recommended; vancomycin is added for clinical or bacteriologic evidence of MRSA, such as severe mucositis, catheter-related sepsis, and hypotension [42]. It is important when choosing empiric regimens to consider recent antibiotic therapy that might have resulted in selection of resistant pathogens. Empiric treatment must be streamlined once the cultures confirm a pathogen to avoid selection of resistant flora.
Therapy of Mixed Bacterial Infections

Combination therapy is necessary to provide a broad effective coverage in specific infections expected to involve diverse microorganisms. For example, intra-abdominal and intrapelvic infections frequently involve complex infecting flora, including aerobic and anaerobic pathogens. Definitive treatment of such infections often includes an extended spectrum β-lactam (ESBL) or a fluoroquinolone for members of the Enterobacteriaceae family; clindamycin or metronidazole for Bacteroides fragilis and other anaerobes; and ampicillin or piperacillin for enterococci. An alternative regimen particularly in the patient with known or suspected (long-term residence in the ICU or recent receipt of broad-spectrum antibiotic therapy) multiresistant gram-negative bacteria is meropenem, imipenem, or piperacillin/tazobactam [28,43].

Fungal Infections

Candida species are among the most common microorganisms isolated from patients with sepsis with 4.6 sepsis cases per 10,000 admissions. Candida bloodstream infections are associated with crude hospital mortality in the range of 40%. Trauma; burns; abdominal surgery; parenteral nutrition; broad-spectrum antibiotics; malignancy; cancer chemotherapy; and immunosuppressive therapy following major organ transplantation are factors that increase the risk of invasive fungal infections [43].

For neutropenic and transplant recipients, fungal pathogens like Aspergillus sp., Fusarium sp., Trichosporon sp., Zygomycetes, Pseudallescheria boydii, and dematiaceous fungi produce severe and often fatal infections [42,44].

Early recognition and aggressive medical therapy are key to the successful treatment of fungal infections.

Multidrug-Resistant Organisms

Antimicrobial multidrug resistance (MDR) is now prevalent all over the world with extreme drug resistance (XDR) and pandrug resistance (PDR) being encountered increasingly often, especially among hospital acquired infections occurring in large highly specialized hospitals treating patients. Gram-negative bacilli resistance is a persistent problem in the ICU [34]. ESBLs have been identified for decades in the Enterobacteriaceae, particularly Klebsiella species, Escherichia coli, and Proteus mirabilis. CRE, or carbapenem-resistant Enterobacteriaceae, are a family of organisms that are difficult to treat because they have high levels of resistance to antibiotics. Klebsiella species and Escherichia coli (E. coli)
are examples of Enterobacteriaceae, a normal part of the human gut bacteria that can become carbapenem-resistant. Types of CRE are sometimes known as KPC (*Klebsiella pneumoniae* carbapenemase) and NDM (New Delhi metallo-β-lactamase). KPC and NDM are enzymes that break down carbapenems and make them ineffective. Both of these enzymes, as well as the enzyme VIM (Verona integron–encoded Metallo-β-lactamase), have also been reported for Pseudomonas CDC. These organisms also typically carry other resistance genes and are frequently resistant to trimethoprim-sulfamethoxazole, fluoroquinolones, and aminoglycosides [34,45]. *Acinetobacter baumannii* is a major hospital-associated pathogen that causes a spectrum of diseases including respiratory tract, bloodstream, urinary tract, surgical site, and wound infections; *Acinetobacter baumannii* has a propensity to acquire resistance to multiple classes of antimicrobial agents, and treatment of infection by highly resistant strains can be extremely difficult [46].

Vancomycin-resistant *Enterococcus* species have emerged in the recent decades as a major nosocomial pathogen for patients with complications of prolonged hospitalization, intravenous lines, intra-abdominal surgery, on mechanical ventilation; or who received broad-spectrum antibiotics that are devoid of activity against enterococci. Linezolid, daptomycin, ceftaroline, and tigecycline are treatment options for the treatment of serious nosocomial infections caused by vancomycin-resistant enterococci [47].

**Treatment of Fever**

Several factors must be considered when determining whether to treat fever symptomatically using antipyretics. Although strong arguments exist for and against the treatment of fever, the currently available randomized trial literature does not support an outcome benefit from a particular fever management strategy. However, antipyretic therapy may relieve discomfort and decrease the metabolic rate associated with fever [48].

We recommend that antipyretic therapy be withheld unless the temperature exceeds 41°C.

Physical methods used to reduce temperature such as cooling blankets, ice packs, and intravascular cooling devices may produce shivering with an increase in metabolic demand and cause patient discomfort [9].

Prevention and Control of Healthcare-Acquired Infections in the Intensive Care Unit
SUMANTH GANDRA • RICHARD T. ELLISON, III

INTRODUCTION
Preventing healthcare-acquired infections in intensive care units (ICUs) is a daily concern of physicians providing care for critically ill patients. Patients in ICUs are at increased risk of infection for multiple reasons including their underlying illness, the use of medical devices for organ system support and hemodynamic monitoring, impaired nutritional status that contributes to immune function compromise, and ongoing exposure to hospital resident antibiotic-resistant bacterial flora. The focus of this chapter is to review the general epidemiology of these infections, the factors contributing to their development, preventive strategies, and important characteristics of key healthcare-acquired pathogens.
Epidemiology of Healthcare-Acquired ICU Infections

Studies performed over the last three decades have found that infections in ICU patients are both common and significant. Work by Craven and colleagues in the early 1980s at Boston City Hospital in adult medical and surgical ICUs found that overall, 28% of the patients developed at least one nosocomial infection, and that infected patients had threefold increases in mortality compared to those not infected [1]. In another single medical ICU study performed in the United States over 20 months in 2000 to 2001, 42% of patients requiring at least 48 hours of ICU care had a microbiologically confirmed infection, and patients with infection had a 1.9-fold increased risk of in-hospital mortality ($p < 0.001$) [2]. Similarly, in 2007, European investigators assessed the prevalence of infections among adults ICUs in a multinational survey involving 14,414 patients in 1,265 ICUs from 75 countries on one single day (the EPIC II Study), and found that 51% of patients were infected [3]. In the same study, the mortality was twice among patients infected than those not infected (25% vs. 11%; $p < 0.001$). More recently, in 2011, a multistate point prevalence survey of healthcare-associated infections by the Centers for Disease Control and Prevention (CDC) from 183 hospitals in the United States involving 11,282 patients found that 34.5% of healthcare-associated infections occurred in ICUs [4].

The types of infection seen in ICU patients have varied slightly over time and between types of ICU units, but several types of infections have predominated. In the Boston City Hospital study, pneumonia, surgical wound infections, urinary tract infections (UTIs), and bloodstream infections (BSIs) were the most frequent infections [1]. Klevens and colleagues, using a multi-step approach, estimated 394,288 hospital-associated infections among adults and children in ICU in 2002 from US hospitals. The infection rate per 1,000 patient-days was 13.0, among all, UTI was the highest (3.38) followed by pneumonia (3.33) and BSI (2.71) [5]. In the EPIC II study, among 7,087 patients with infection in adult ICUs, the principal site of infections were respiratory tract (63.5%), abdomen (19.6%), bloodstream (15.1%) and urinary tract (14.3%) [3]. The use of medical devices is a predominant cause of infection in the ICU setting, and major concerns are pneumonia associated with mechanical ventilation, UTIs associated with urinary catheterization, and primary BSIs linked to central venous catheters.

The National Healthcare Safety Network (NHSN) of the CDC assesses device-associated infections in various types of ICUs in the US yearly.
using standardized surveillance definitions. According to NHSN data, in 2013 the pooled mean of central line–associated bloodstream infections (CLABSI) in various ICUs was 0.99 per 1,000 central line days [6]. Similarly, for catheter-associated urinary tract infections (CAUTI) in 2013, the pooled mean was 2.3 per 1,000 urinary catheter days but with a higher mean of 5.3 per 1,000 central line days in neurosurgical units [6]. For ventilator-associated pneumonia (VAP), in 2012, the pooled mean was 1.32 per ventilator days with the highest rate in burn units and lowest in pediatric cardiothoracic units [7]. The variation of rates for device-associated infections between different types of critical care units is likely related to the size of the unit (small vs. large), the type of more predominant device use (urinary catheters, endotracheal tubes, and vascular catheters), the age group of the patients (pediatric vs. adults), and the most predominant illness of the patients (coronary, surgical, burn, medical, pediatric). Pediatric ICUs differ from adult ICUs in many ways. First, they are typically combined units (medical and surgical). Second, their beds are not commonly physically separated as in adult ICU beds. Third, pediatric patients usually have less comorbid conditions than adults.

Infections rates in ICUs among developing countries are high when compared to developed countries. A systematic review of studies on healthcare-associated infections in developing countries from 1995 through 2008 reported a healthcare-associated infection density in adult ICUs as 47.9 per 1,000 patient-days, which is three times that of US ICUs [8]. More recently, the International Nosocomial Infection Control Consortium (INICC) surveillance study from January 2007 through December 2012 reported on device-associated healthcare-associated infections in 503 ICUs in 43 countries from Latin America, Asia, Africa, and Europe [9]. In this study, the device utilization rates in ICUs in developing countries were similar to those of the United States; however, infection rates were significantly higher. In corresponding ICUs, the pooled rate of VAP was nearly 16 times (16.8 vs. 1.1 per 1,000 ventilator days), CLABSI was five times (4.9 vs. 0.9 per 1,000 central line days) and CAUTI was nearly four times (5.5 vs. 1.3 per 1,000 catheter days) the US rates in 2012 [9].
MICROBIOLOGY OF ICU INFECTIONS

The predominant causes of ICU infections are a limited number of bacterial and fungal pathogens. In general, the pathogens that are seen can be characterized as those that survive well in a moist environment (e.g., gram-negative bacteria including *Enterobacter* strains, *Pseudomonas aeruginosa*, and *Acinetobacter* species), those that colonize the skin and produce biofilm to allow adherence to catheters and other devices (e.g., *Staphylococcus aureus* and coagulase-negative staphylococci), and those which are resistant to commonly used antibiotics (e.g., methicillin-resistant *S. aureus* [MRSA], vancomycin-resistant enterococci [VRE], multidrug-resistant [MDR] gram-negative bacteria, and Candida species). In the EPIC II study, gram-negative organisms were predominantly isolated (62%), followed by gram-positive (47%) and fungal organisms (19%). Among gram-positives, *S. aureus* was most common (20%), and among gram-negative organisms *Pseudomonas* species were most commonly isolated (20%) followed by *Escherichia coli* (16%). Overall, *S. aureus* was the single most common organism isolated (20%) and 50% of these strains were MRSA [3]. The NHSN 2009 to 2010 data on healthcare-associated infections occurring in both ICU and non-ICU settings show that *S. aureus* was the most common (15.6%) organism isolated, followed by *E. coli* (11.5%) and coagulase-negative *Staphylococci* (11.4%) [10]. When reviewed by type of infection, in CLABSIs, the coagulase-negative *Staphylococci* were the most common organisms followed by *S. aureus*. In CAUTIs, *E. coli* was the most common pathogen followed by *P. aeruginosa*, and in VAP, *S. aureus* was the most common organism followed by *P. aeruginosa*. In contrast to US NHSN data, the INICC surveillance study of developing countries showed that all device-associated infections were predominantly caused by gram-negative organisms. In CLABSIs, *Klebsiella pneumoniae* was the most common organism followed by *Acinetobacter baumannii*; for CAUTIs, *E. coli* was the most common organism followed by *K. pneumoniae*; and for VAP, *A. baumannii* was the most common organism followed by *P. aeruginosa* [9].

Antimicrobial resistance patterns among the pathogens seen with device-associated infections for both the United States and developing countries show a high frequency of MDR organisms [9,10]. Although there is variation among institutions and sites of infections, common
pathogens reported in the NHSN and INICC data include MRSA, VRE, third-generation cephalosporin-resistant Enterobacteriaceae, and MDR P. aeruginosa and A. baumannii. In addition, carbapenem-resistant Enterobacteriaceae are being seen more frequently.
RISK FACTORS

The length of ICU stay is the predominant risk factor for nosocomial infection followed by the use of medical devices. In the EPIC II study, the infection rate increased from 32% for patients with ICU stay of 0 or 1 day prior to the study day to more than 70% in patients with ICU stay of more than 7 days prior to the study day [3]. The NHSN nosocomial infection rates for pneumonia, BSIs, and UTIs have correlated strongly with device usage [5,11]. Other risk factors identified in the EPIC II study include the severity of patient’s underlying illness, increasing age, renal replacement therapy, and presence of comorbid conditions (like chronic obstructive pulmonary disease (COPD), cancer, HIV, and immunosuppression). Teaching hospitals with higher rates of device utilization have had higher device-associated infection rates [5,11]. Similar to adults, risk factors for nosocomial infection for pediatric ICU patients include length of stay in ICU, rate of device utilization, severity of underlying illness, and parenteral nutrition [12].

Hyperglycemia has also been considered a risk factor for infections in the ICU. Hyperglycemia is common in the ICU setting because of underlying disease, physiologic stress, and parenteral nutritional support. In vitro investigations suggest that hyperglycemia can impair polymorphonuclear leukocyte and monocyte phagocytic and bactericidal activities [13]. However, this assumption has not been confirmed as both systematic reviews and meta-analyses have found no effect of intensive glucose control on the infection rates of ICUs [14,15].
PREVENTIVE AND CONTROL MEASURES

A number of approaches have been found to help prevent ICU-associated infections. The comprehensive use of standard infection control practices as well as enhanced infection control precautions for selected pathogens, limiting the use of medical devices, and careful attention to architectural design are key components of strategies to prevent ICU infections. Additionally, the implementation of targeted quality improvement programs for central vascular catheter infections and VAP has been shown to be an highly effective approach for decreasing infection rates.

Infection Control Precautions

Isolation Precautions

The CDC and the Hospital Infection Control Practices Advisory Committee have prepared guidelines on isolation precautions to prevent the transmission of microorganisms from colonized or infected patients to other patients, visitors, and health care workers (HCWs) [16]. The current guidelines were last updated in 2007, and recommend a two-tiered approach to patient care. Standard precautions are used for the care for all patients. Additional more stringent transmission-based precautions are used for the care of patients who are suspected or known to be colonized or infected with specific pathogens that are readily transmitted either through direct contact, through large respiratory droplets, or through smaller airborne particles. The current guidelines are summarized in Table 72.1. Contact precautions are commonly used in ICUs to decrease the transmission of MDR bacteria such as MRSA, VRE, extended-spectrum beta-lactamase (ESBL)-producing bacteria, and carbapenem-resistant gram-negative bacteria. However, routine use of contact precautions for all patients in ICUs is debatable. A recent large cluster randomized study found that the universal use of contact precautions for all ICU patients did not reduce the primary combined end point of MRSA or VRE acquisition compared to baseline rates, although this study did not assess acquisition of other antibiotic-resistant organisms [17].

**Hand Hygiene**

A key component of these infection control guidelines is the need for healthcare workers to practice good hand hygiene [16,18]. Approaches that have been shown to improve compliance with this practice have included the provision of water-free alcohol-based hand rubs throughout institutions, an intensified educational programs on hand hygiene, and
electronic monitoring programs [19,20] Alcohols have excellent in vitro germicidal activity against gram-positive and gram-negative pathogens, fungi, and many viruses including HIV, influenza virus, and respiratory syncytial virus (RSV). Alcohol-based hand rubbing is recommended in all clinical situations except when the hands are visibly soiled. Alcohol is inactive against Clostridium difficile spores. However, there has been no association between the use of alcohol-based hand hygiene and the incidence of C. difficile disease [21]. Consequently, other than in outbreak settings, routine alcohol-based hand hygiene is still recommended when caring for C. difficile patients [22]. An ongoing issue remains the relatively low rate of hand hygiene activity by healthcare workers and ongoing effort is necessary to promote this practice.

Antimicrobial Bathing

Patients in the ICU are major reservoirs of MDR organisms and decreasing this reservoir would lead to a decrease in the risk of nosocomial transmission. Accordingly, recent work has assessed the performance of daily bathing of patients with chlorhexidine gluconate using either impregnated clothes or dilute bathing solutions. Both a meta-analysis and several multicenter trials have found that this approach can decrease the incidence of BSIs and contribute to reducing transmission of MDR organisms [23–26]. However, a recent pragmatic trial in a single center that already had a low incidence of healthcare-acquired infections did not find additional benefit to this practice [27].

Environmental Cleaning

Although not associated with alterations in infection rates, the institution of programs to monitor the actual performance of housekeeping staff has been found to improve disinfection in the hospital environment in ICUs, including disinfection of computer stations [28]. “No touch” automated room disinfection methods using hydrogen peroxide vapor or ultraviolet (UV) light have been shown to reduce the rate of pathogen transmission between patients compared to conventional cleaning methods [29–32]. Whether this reduced rate of pathogen transmission among ICU patients using automated room disinfection methods would result in a significant reduction in the occurrence of healthcare-associated infections is yet to be shown. Still, several single-center retrospective studies using automated room disinfection methods have reported a significant decrease in hospital acquisition of MDR organisms and C. difficile, and there is a need for prospective multicenter cluster randomized studies to confirm these findings [33–36].
In addition to these automated disinfection methods, there has been interest in self-disinfecting antimicrobial surfaces because of the potential ability to prevent recolonization by microorganisms. Recently, a randomized control study in the United States in three ICUs in three hospitals showed a significant reduction in the incidence of hospital-acquired infections and or MRSA or VRE colonization (0.071 vs. 0.128; \( p = .020 \)) among patients admitted to patient rooms with copper alloy on high touch surfaces [37]. However, additional randomized control studies are needed to confirm the efficacy of this expensive approach.

Randomized control trials involving various infection prevention measures and their findings are summarized in Table 72.2.

**Architectural Design and Hospital Construction**

Modern ICU design includes the use of single patient rooms, adequate physical space for equipment and personnel, individual patient sinks, adequate hand hygiene stations, and adequate room ventilation with filtered air and at least six air changes per hour [38]. Additionally, there are defined guidelines for the design of airborne isolation infection rooms for patients requiring management of tuberculosis or other infections readily transmitted by the airborne route.

Ongoing construction and renovation activities in healthcare facilities
have also been recognized as significant risk factors for infections with environmental pathogens. There can be concerns with environmental gram-negative organisms, particularly *Legionella* species. More frequent is a concern with disease caused by environmental molds, in particular *Aspergillus* species [38,39]. US healthcare institutions are now required to have procedures in place to ascertain that construction and renovation activities are performed in a manner that protects patients from being exposed to environmental pathogens [38].

**Infection Control Surveillance Programs**

In 1970, the CDC initiated the National Nosocomial Infection Surveillance system (NNIS) as an approach to identifying secular trends in these infections. The program initially included 10 to 20 hospitals, but expanded to nearly 300 hospitals. Subsequent studies that analyzed healthcare-acquired infection rates at differing institutions before and after the distribution of infection rate data found that institutional infection rates diminished after institutions were made aware of their infection rates [40,41]. In the last 5 years, all US hospitals have been required to report hospital-acquired infection rates to the second-generation surveillance program, the NHSN, and with this requirement there has been an ongoing reduction in the rate of CLABSIs nationally [11,42]. Disseminating data in a simple and routine manner, to those who need to know, enables clinicians to make decisions on the basis of scientific data and to alter practice.

**Quality Improvement Initiatives**

A major advance in medical care in the last decade has been the adoption of quality improvement strategies used in other industries such as air transportation. The development of standardized approaches to the provision of care has been particularly effective in the prevention of device-related infections in the ICU setting. Several institutions have documented a significant reduction in BSIs linked to central venous catheters after the implementation of quality improvement programs targeted against these infections [43,44]. Principal components of these programs have included providing education on appropriate infection control practices to staff involved in central catheter placement and care, standardizing the location of catheter placement to preferentially use the subclavian location and avoid femoral lines when possible, centralizing the location of all equipment required for catheter placement, the use of
maximal sterile-barrier precautions (i.e., use of cap, surgical masks, sterile gowns, sterile gloves, and large sterile drapes) during catheter insertion, and trying to remove these catheters as quickly as possible [44–47].

A similar approach has been taken to prevent VAP in the ICU with the use of targeted education programs [48–50]. These quality improvement education programs have in general followed CDC guidelines on measures to prevent healthcare-acquired pneumonia and have been directed at medical staff, ICU nursing staff, and respiratory therapists. Key elements of the program include a focus on hand hygiene, maintaining the patient in a semi-recumbent position with the head of the bed elevated 30 degrees, standardizing the approach to changing ventilator circuitry, avoiding nasal intubations, avoiding gastric distension, removing nasogastric tubes, and weaning patients as rapidly as possible [48].
SELECTED HEALTHCARE-ACQUIRED PATHOGENS

Clostridium Difficile-Associated Colitis

*C. difficile* is the most frequent etiology for healthcare-acquired diarrhea. In 2011, an estimated 453,000 cases and 29,300 deaths occurred in the United States with more than two-thirds of cases being healthcare associated [51]. The organism may asymptptomatically colonize the gut or cause illness extending from watery diarrhea through pseudomembranous colitis, toxic megacolon, perforation, and even death [52,53]. Transmission in the healthcare setting appears to occur through transient hand carriage of HCW, close contact with other colonized or infected patients, or exposure to spores present on contaminated environmental surfaces [53,54]. Exposure to antibiotics increases the risk of developing disease. Practically all antibiotics have been implicated in the development of clostridium difficile associated diarrhea (CDAD), but disease is especially common with clindamycin, penicillins, and cephalosporins.

At least part of the increasing incidence can be linked to the spread of a specific *C. difficile* strain, BI/NAP1/027, which is associated with severe disease, excess mortality, and epidemic outbreaks [55,56]. In 2011, among 453,000 *C. difficile* cases, NAP1/027 accounted for an estimated 30.7% and 18.8% of the healthcare and community-associated infections, respectively [51]. It is unclear why this strain has spread so widely; however, there is evidence that it has increased virulence because of increased production of the *C. difficile* A and B toxins, and has also acquired resistance to fluoroquinolone antibiotics which are used widely for treatment of UTI and community-acquired pneumonia [57].

Approaches to the prevention of CDAD are directed toward preventing horizontal transmission of the pathogen, as well as reducing the individual patient’s risks of disease if they acquire the organism through the judicious use of antibiotic therapy. Barrier methods remain fundamental to prevention of spread, as well as the use of private rooms or cohorting CDAD patients. Alcohol hand hygiene preparations are not active against bacterial spores, including those of *C. difficile*, but clinical studies have shown no association between the use of alcohol-based hand hygiene and the incidence of *C. difficile* [21]. Therefore, the use of soap and water for enhanced mechanical clearance during hand hygiene should be considered in the setting of increased transmission of *C. difficile* [22]. Healthcare workers should wear gloves when caring for
patients with CDAD, and the use of gowns is also recommended when soiling of the patient’s cloth is likely [18,58]. In addition to the above infection control measures, implementing antimicrobial stewardship programs which limit inappropriate antibiotic use has been associated with decreases in the incidence of CDAD [59,60].

Thorough environmental cleaning is critical, as *C. difficile* spores can live for several months on hospital dry surfaces. Commonly used hospital cleaning agents such as quaternary ammonium–based detergents are ineffective in killing *C. difficile* spores [61]. Use of 10% sodium hypochlorite solution is effective in reducing environmental contamination with *C. difficile* spores and is associated with decreased *Clostridium difficile* infection (CDI) rates [62,63]. Other novel strategies reported for environmental decontamination include hydrogen peroxide vapor, UV light decontamination, and copper-coated surfaces [36,64,65]. Whether these approaches will decrease nosocomial CDI rates remains to be studied in clinical trials.

**Methicillin-Resistant Staphylococcus Aureus**

The prevalence of MRSA in ICUs in the United States has risen, from an incidence of 30% to 40% in the middle of the 1990s to over 60% in 2004 [66]. However, compared to 2005, the estimated national incidence of hospital-onset MRSA infections in the United States in 2011 decreased by 54% (9.91 vs. 4.54 cases per 100,000 persons) [67]. Similarly, all-cause mortality rates due to hospital-onset invasive MRSA infections decreased from 2.7 per 100,000 persons in 2005 to 1 per 100,000 persons in 2011 [67]. The decrease in incidence is likely due to increased implementation of infection prevention measures, especially targeting intravascular catheter-related infections [68]. There has been also a change in the frequency of infections caused by different MRSA strains. Infections due to community-associated MRSA strains are increasing in hospital settings (including ICUs), are becoming endemic, and are replacing the traditional hospital strains of MRSA [69,70]. Risk factors associated with acquisition of healthcare-acquired strains of MRSA include recent hospitalization, hemodialysis, and residence in a long-term facility or injection drug use.

Current CDC guidelines recommend the use of “contact precautions” for patients known or suspected to be colonized with epidemiologically important organisms [16]. However, the use of contact precautions for endemic MRSA remains controversial [71,72]. Contact precautions have been used as a part of multiple control measures and unfortunately, there are no randomized control trials comparing contact precautions versus standard precautions alone in the acquisition of MDR organisms. Few quasi-experimental before and after studies report no change in MRSA or
VRE transmission and no change in rates of MRSA or VRE device-associated infections with removal of contact precautions for MRSA and VRE-colonized or infected patients [73,74]. In addition, a recent cluster randomized study on measures to prevent MRSA infections found that “vertical” measures targeting a specific organism were inferior to “horizontal” measures active against multiple organisms such as universal decolonization and daily chlorhexidine bathing [26]. However, in the setting of outbreaks of MRSA, institutions may also consider instituting patient/staff cohorting, decolonization of patients with topical nasal mupirocin and total body chlorhexidine baths/showers, and screening healthcare workers for MRSA colonization [75]. Enhanced infection control policy with stringent contact precautions has been recommended for patients with vancomycin-resistant S. aureus (VRSA) [76].

Vancomycin-Resistant Enterococci

VRE was first recognized in Europe in 1988 and in the United States soon thereafter. By 1993, there was a 20-fold increase in VRE prevalence in ICUs in the United States [77]. A recent meta-analysis of 37 published studies estimated that the prevalence of VRE on admission to adult ICUs was 8.8% [78]. In 2009 to 2010 NHSN data, 84% and 82% of Enterococcus faecium isolates obtained from CLABSI and CAUTI, respectively, were vancomycin resistant. Whereas, 9% and 6% of Enterococcus faecalis isolates obtained from CLABSI and CAUTI, respectively, were vancomycin resistant [10]. Although not as virulent a pathogen as MRSA, VRE can cause infections in the debilitated ICU patient. Also, as the gene inducing vancomycin resistance in VRE, vanA, can be transferred to S. aureus, the presence of VRE in ICU patients increases the potential for the emergence of VRSA strains [79]. Risk factors for VRE colonization are previous hospitalization, glycopeptide administration, colonization pressure, and patients with comorbid conditions [80]. Similar to MRSA, the use of contact precautions for endemic VRE remains controversial and there are no randomized control trials comparing contact precautions versus standard precautions alone in the acquisition of VRE. Quasi-experimental studies involving removal of contact precautions for patients colonized or infected with VRE did not have effects on VRE transmission or device-associated infection rates [73,74]. Horizontal measures probably play a more significant role than contact precautions in limiting the transmission of VRE.
Multidrug-Resistant Gram-Negative Bacilli

According to NHSN, gram-negative bacteria belonging to Enterobacteriaceae family and organisms like *P. aeruginosa* and *A. baumannii* are frequent cause of healthcare-associated infections in 2009 to 2010 in the United States [10]. There is a growing concern of increasing multidrug resistance among gram-negative bacteria, particularly the rapid global spread of carbapenem-resistance caused by carbapenemases in Enterobacteriaceae (CRE) [81]. This has been facilitated by mobile genetic elements harboring genes encoding for carbapenemases such as *Klebsiella pneumoniae* carbapenemase (KPC) and metallo-β-lactamases (like New Delhi Metallo-β-lactamase-1—NDM1). The proportion of CRE isolation in healthcare-associated infections increased from 1.2% in 2001 to 4.2% in 2011 in NNIS/NHSN [82]. This is concerning because of the frequency of infections caused by the Enterobacteriaceae family, limited number of options for treating CRE infections, and high mortality associated with these infections. The risk factors for acquisition of CRE include ICU stay, residence in long-term acute care (LTAC) facilities, presence of indwelling devices, antimicrobial exposure (carbapenems, extended-spectrum cephalosporins, fluoroquinolones), CRE colonization pressure, severity of illness, and immunosuppression/organ transplantation [83–86]. Current CDC interim surveillance definition (which could be subjected to change soon) for CRE includes any Enterobacteriaceae that is non-susceptible to one of the three carbapenems (doripenem, meropenem, imipenem) and resistant to all three third-generation cephalosporins (ceftriaxone, cefotaxime, and ceftazidime) [87]. Currently, active surveillance for asymptomatic rectal CRE colonization is not recommended routinely. However, it can be considered in the setting of an outbreak and for high-risk patients (admission to LTAC facilities, ICUs). Infection control measures for patients colonized or infected with CRE should include strict contact precautions, minimizing use of invasive devices, antimicrobial stewardship, and other general measures like hand hygiene and chlorhexidine bathing [87].

*P. aeruginosa* is the fifth most common pathogen isolated from device-associated healthcare-associated infections in 2009 to 2010 NHSN data. MDR *P. aeruginosa* isolates ranged from a minimum of 5% in surgical site infections to a maximum of 18% in VAP [10]. Similarly, *A. baumannii* is one of the most common pathogens isolated from device-associated healthcare-associated infections. Overall, it is the fourteenth most common organism isolated from device-associated infections and it is the fifth most common gram-negative pathogen isolated from VAP in 2009 to 2010 NHSN data. MDR *A. baumannii* isolates ranged from a minimum of 44% for surgical site infections to a maximum of 78% for
Unfortunately, this organism survives well in the environment, and has been associated with significant ICU outbreaks. Infections due to this organism are associated with poor outcomes, including higher rates of morbidity and mortality, and higher medical expenses. Control measures involve the use of “contact precautions” and enhanced environmental cleaning efforts [16,88].

Given this rapidly increasing incidence of resistant gram-negative strains, it is important for institutions to track rates of antibiotic resistance in their ICUs independent of overall institutional antibiotic resistance rates. Empiric antibiotic coverage for gram-negative pathogens in given ICUs should be targeted at the known gram-negative pathogens present in the environment. Enhanced infection control contact precautions should be used for patients who are colonized or infected with ESBL- or KPC- or NDM-positive gram-negative pathogens or MDR P. aeruginosa or A. baumannii.

**PENICILLINS**

The classes of penicillins include penicillin G, ampicillin, the antistaphylococcal (semisynthetic) penicillins, and the expanded spectrum (antipseudomonal) penicillins alone and in combination with a β-lactamase inhibitor [1]. The serum half-life ($t_{1/2}$) of most penicillins is short, and rapid clearance occurs via the kidneys. Some semisynthetic penicillins, particularly nafcillin and oxacillin, are metabolized to a large extent by the liver; therefore, adjustment in dosage is not required in patients with renal insufficiency; for piperacillin, dosing adjustment is necessary only in severe renal insufficiency. For most other penicillins, moderate adjustments should be made in dosage for patients with severe renal insufficiency (Table 73.1). Penicillins are relatively nontoxic at usual doses, and side effects most commonly involve hypersensitivity reactions. Bone marrow and hepatic toxicity caused by semisynthetic penicillins have been described, with neutropenia more commonly seen with nafcillin and hepatitis more likely to occur with oxacillin.

**Penicillin G**

In the ICU, aqueous penicillin G is appropriate in the therapy of severe, overwhelming infections caused by susceptible organisms, including pneumococcal pneumonia and bacteremia caused by penicillin-susceptible strains [1], such as necrotizing fasciitis due to group A *Streptococcus* (in combination with clindamycin), and for streptococcal bacteremia. Because of the prevalence of penicillin-resistant pneumococci, life-threatening infections (especially meningitis) due to these organisms should be treated initially with ceftriaxone, cefotaxime, or vancomycin [2]. Although aspiration pneumonia commonly involves mouth anaerobes that are susceptible to penicillin G, penicillin-resistant anaerobes can be found in putrid, cavitary pneumonia and empyema, and clindamycin with or without a third-generation cephalosporin (or an extended-spectrum β-lactam plus metronidazole) is the preferred regimen [3,4]. Therapy for penicillin-susceptible *Enterococcus* spp causing endocarditis is penicillin G or ampicillin plus an aminoglycoside, generally gentamicin [5]. The activity of penicillin G and ampicillin against most Gram-negative bacilli is poor. *Staphylococcus aureus* should be presumed to be resistant to penicillin, ampicillin, and piperacillin, as most strains produce a penicillinase.
Penicillinase-Resistant Semisynthetic Penicillins

Because most strains of *S. aureus* are resistant to penicillin G by virtue of β-lactamase production, treatment of severe infections caused by these organisms involves one of the β-lactamase–resistant penicillins (see Table 73.1). Nafcillin and oxacillin are interchangeable. Both exhibit excellent in vitro activity against most susceptible isolates of *S. aureus*, but are less active (although generally effective) than penicillin G against streptococci. Both are sufficiently metabolized by the hepatic route such that no adjustment in dose is necessary for patients with renal insufficiency. Because of the high prevalence of community-acquired methicillin-resistant *S. aureus* (MRSA), vancomycin should be used for empiric therapy of suspected staphylococcal infections [6]. In patients with overwhelming or disseminated infection caused by β-lactam–susceptible *S. aureus*, therapy should be instituted with 9 to 12 g per day of intravenous (IV) oxacillin or nafcillin, in divided doses every 4 hours (see Table 73.1).

---

Anti–Gram-Negative Penicillins

The expanded-spectrum penicillin (piperacillin) and the combination agent piperacillin/tazobactam exhibit activity against many *Enterobacteriaceae* that are resistant to ampicillin [7]. In the ICU patient with suspected bacteremia or overwhelming infection due to Gram-negative bacilli, therapy should be chosen with knowledge of local ICU resistance patterns and include agents that the patient has not received recently. Pharyngeal colonization with Gram-negative bacilli develops rapidly among patients in the ICU, and initial therapy of nosocomial aspiration pneumonia requires the addition of an antipseudomonal penicillin, carbapenem, or cephalosporin, usually in combination with an aminoglycoside or fluoroquinolone [8,9]. For patients with *Pseudomonas aeruginosa* infections, the intensivist should consider using higher dosages or continuous infusions of piperacillin/tazobactam or piperacillin, with or without an aminoglycoside. The addition of the aminoglycoside to extended-spectrum penicillins is controversial [10] but has been shown to provide broader Gram-negative coverage and synergistic killing against *P. aeruginosa*.

β-Lactamase–Inhibitor Combinations
Clavulanic acid, sulbactam, and tazobactam are β-lactamase inhibitors that bind irreversibly to β-lactamases derived from S. aureus and anaerobes, as well as some β-lactamases from Gram-negative bacilli. Thus, the combination of one of these β-lactamase inhibitors with ampicillin or piperacillin results in a drug combination that is active against β-lactamase–producing strains of S. aureus, Bacteroides sp, Haemophilus influenzae, Neisseria gonorrhoeae, and enteric Gram-negative bacilli such as Escherichia coli, Klebsiella spp. and Proteus spp. However, chromosomally mediated β-lactamases of other Gram-negative bacilli are unaffected by these β-lactamase inhibitors, and therefore these combinations are ineffective against many isolates of P. aeruginosa, Enterobacter cloacae, Citrobacter freundii, and Serratia marcescens.

Formulations of β-lactamase combinations available parenterally include ampicillin/sulbactam and piperacillin/tazobactam. Piperacillin/tazobactam can be effective in the treatment of mixed infections, such as nosocomial pneumonia, intra-abdominal infections, and synergistic skin soft tissue infections. However, depending on local resistance patterns, the lack of efficacy against multiple-resistant Gram-negative bacilli commonly found in the ICU warrants monitoring of local resistance patterns and use of a carbapenem, or adding an aminoglycoside as part of a combination regimen to ensure broad efficacy against nosocomial Gram-negative bacilli [8,9].

The usual suggested dosages of the available combinations are presented in Table 73.1. For treatment of P. aeruginosa infections, the dosage of piperacillin/tazobactam should be increased to 3.375 g IV every 4 hours or 4.5 g IV every 6 hours for pneumonia. The pharmacology of the β-lactamase inhibitors is similar to that for other β-lactams: Clearance is by renal mechanisms, and dosage adjustments must be made with these combinations in the setting of renal impairment. Continuous infusion of piperacillin/tazobactam after a bolus has a pharmacodynamic advantage for organisms with relatively high minimum inhibitory concentrations (MICs) to piperacillin and for patients on continuous venovenous hemofiltration (CVVH).
CEPHALOSPORINS

Cephalosporin antibiotics exhibit relative safety and an antibacterial spectrum that includes activity against Gram-positive and Gram-negative bacteria. Examples of parenteral cephalosporins that are currently available are listed in Table 73.2. Cephalosporins are not active against MRSA, Enterococcus spp, or Stenotrophomonas maltophilia. Many strains of Enterobacter possess an inducible chromosomal β-lactamase and may become resistant during therapy.

**First-Generation Cephalosporins**

First-generation cephalosporins exhibit a virtually identical spectrum of antibacterial activity, and they differ only in their pharmacokinetic properties. These agents are active against staphylococci (β-lactam–susceptible staphylococci) but are not effective against enterococci, *Listeria monocytogenes*, MRSA, or the majority of coagulase-negative staphylococci. Community-acquired strains of *E. coli*, *Proteus mirabilis*, and *Klebsiella pneumoniae* often are susceptible to the first-generation cephalosporins, but in general, third-generation agents are far more potent against Gram-negative bacilli and are preferred in the treatment of such infections in ICU patients. Nosocomial isolates of *Enterobacteriaceae* usually are resistant to first-generation cephalosporins, as are *Pseudomonas* and *Acinetobacter* spp.

**Second-Generation Cephalosporins**

Second-generation cephalosporins (e.g., cefuroxime) have only limited activity against hospital-acquired Gram-negative bacilli and therefore are not recommended for treatment of Gram negatives in the ICU setting.

**Third-Generation Cephalosporins**

Third-generation cephalosporins exhibit an expanded spectrum and increased potency against Gram-negative organisms, especially *Enterobacteriaceae*. A number of these agents, particularly ceftazidime,
are less active than first-generation cephalosporins against Gram-positive cocci. However, ceftriaxone has significant activity against Strep\(t\)tococcus pneumoniae and other oral streptococci, and has been recommended for use in severely ill patients with community-acquired pneumonia (CAP), bacterial meningitis, and bacterial endocarditis \([5,11,12]\).

The activity of most third-generation cephalosporins against \(P.\) aeruginosa is variable and unpredictable; only ceftazidime and cefepime, a fourth-generation cephalosporin, are considered active against this organism and should be used in combination with an aminoglycoside when infection with \(P.\) aeruginosa is likely \([13]\). If a third-generation cephalosporin is used as a single agent, gaps in coverage may occur, including: (a) enterococcal superinfection; (b) \(P.\) aeruginosa infections in neutropenic patients; (c) emergence of broad-spectrum resistance by means of chromosomally mediated inducible β-lactamases during cephalosporin monotherapy of deep-seated infections by species of Enterobacter, Providencia, Serratia, Pseudomonas, and Acinetobacter; (d) intra-abdominal or intrapelvic infections likely to involve Bacteroides fragilis; and (e) \(S.\) aureus bacteremia, endocarditis, or meningitis. Thus, in ICU patients, third-generation cephalosporins generally should be used empirically as part of combination therapy or as specific single-agent treatment of Gram-negative bacillary infections involving organisms documented to be susceptible to the agent in vitro.

Newer Cephalosporins

Cefepime, a fourth-generation cephalosporin \([14]\), has activity against Gram-positive organisms similar to that of cefotaxime and ceftriaxone and activity against Pseudomonas similar to that of ceftazidime. Compared with third-generation cephalosporins, cefepime has a lower affinity for β-lactamases and is not an inducer of chromosomal β-lactamases. The pharmacokinetics of cefepime are similar to those of ceftazidime: \(t_{1/2}\) is 2.1 hours, and 80% to 90% of the dose is recovered in the urine. For treatment of infections due to \(P.\) aeruginosa, cefepime (often in conjunction with an aminoglycoside) should be dosed every 8 hours, but for moderate infections due to more susceptible species, it can be dosed every 12 hours (see Table 73.2).

Ceftaroline is indicated for treatment of acute bacterial skin and skin structure infections caused by susceptible isolates of the following Gram-positive and Gram-negative microorganisms: \(S.\) aureus (including methicillin-resistant isolates), \(S.\) pyogenes, \(S.\) agalactiae, \(E.\) coli, \(K.\) pneumoniae, and \(K.\) oxytoca \([15]\). It is also approved for the treatment of community-acquired bacterial pneumonia caused by susceptible isolates of \(S.\) pneumoniae (including cases with concurrent bacteremia), \(S.\) aureus (methicillin-susceptible isolates only), \(H.\) influenzae, \(K.\)
pneumoniae, K. oxytoca, and E. coli. Ceftaroline is infused over 1 hour at dose 600 mg IV every 12 hours. Ceftaroline is primarily excreted by urine (88%). In patients with renal impairment dose adjustment is needed (Table 73.2).

Adverse Reactions

Cephalosporins are relatively nontoxic agents. The most commonly noted adverse effects are hypersensitivity reactions, including rashes, fever, interstitial nephritis, and anaphylaxis. In patients with documented penicillin allergy, the risk of cross-reactive allergic reactions to the cephalosporins is cited as 5% to 10%, and generally it is felt that cephalosporins should be avoided for patients with a history of documented anaphylaxis or immediate hypersensitivity (urticaria) reaction to the penicillins, but can be given to patients with a history of other types of reactions to penicillins, including morbilliform rash and fever. Enterococcal superinfections occur with any of the extended-spectrum cephalosporins because none of these agents has significant activity against enterococci [16].

Dosage

When used in the treatment of severe infections in ICU patients, all cephalosporins should be used, at least initially, at maximal doses and short dosing intervals (Table 73.2). In patients with severe impairment of renal function, dosages of all cephalosporins except ceftriaxone must be adjusted to avoid accumulation.

Cephalosporins with β-Lactamase Inhibitor Activity

Ceftazidime/avibactam is a combination of a third generation cephalosporin with a novel non-β-lactam β-lactamase inhibitor (avibactam) [17]. Ceftazidime has bactericidal activity against most Gram negative organism including P. aeruginosa as it arrests bacterial growth by binding to one or more penicillin-binding proteins, thereby inhibiting final transpeptidation steps of peptidoglycan synthesis in bacterial cell-wall. The addition of avibactam protects ceftazidime from degradation by β-lactamase enzymes and effectively extends the antibiotic spectrum of ceftazidime against isolates which are carbapenem resistant due to KPC (Ambler classes A, C, D) or that express ESBL’s or AmpC. Currently, ceftazidime/avibactam is approved by US Food and Drug Administration
(FDA) for treatment of complicated intraabdominal infections and complicated urinary tract infection. In a phase 2 clinical trial in patients with complicated intraabdominal infections, ceftazidime/avibactam at a dose 2.5 g (2 g ceftazidime and 0.5 g avibactam) IV every 8 hours in combination with metronidazole (500 mg IV every 8 hours) provided similar efficacy to meropenem. In patients with complex urinary tract infection, ceftazidime/avibactam (500 mg ceftazidime and 125 mg of avibactam) IV every 8 hours and imipenem-cilastatin provided similar efficacy and safety profile. In patients with ceftazidime-resistant pathogens, 85.7% (6/7) and 81.8% (9/11) had favorable microbiological response at test of cure for the ceftazidime-avibactam and imipenem/cilastatin groups, respectively. Since ceftazidime/avibactam is excreted primarily by the kidney, renal dose adjustment is required in patients with renal impairment (Table 73.2).

Ceftolozane/tazobactam is a novel antipseudomonal cephalosporin combined with a well-established β-lactamase inhibitor. The chemical structure of ceftolozane is similar to that of ceftazidime, with the exception of a modified side-chain at the 3-position of the cephem nucleus, which confers potent antipseudomonal activity. Ceftolozane is distinguished from other cephalosporins by its potent activity versus *P. aeruginosa*, as well as *A. baumanii* and carbapenem-, piperacillin/tazobactam-, and ceftazidime-resistant isolates. The addition of tazobactam extends the activity of ceftolozane to include most ESBL producers as well as some anaerobic species. Ceftolozane/tazobactam is approved for treatment of complicated intraabdominal infections at a dose of 1.5 g (1 g ceftolozane and 0.5 g tazobactam) IV every 8 hours in combination with metronidazole (500 mg IV every 8 hours) and for treatment of patients with complicated urinary tract infections [18]. In a phase 3 clinical trial for treatment of complicated intraabdominal infection ceftolozane/tazobactam 1.5 g IV every 8 hours with metronidazole was noninferior to meropenem by clinical cure rates [19]. Overall, incidence of adverse events were similar for both groups. Ceftolozane/tazobactam is excreted primarily by the kidney, with ceftolozane being eliminated unchanged and tazobactam being hydrolyzed to inactive metabolite. Renal dose adjustment is required (Table 73.2).
CARBAPENEMS

Four carbapenem antibiotics—imipenem, meropenem, ertapenem, and doripenem—are approved for clinical use [20,21]. Imipenem is administered in combination with cilastatin, an enzymatic inhibitor of a renal dehydropeptidase, which inhibits metabolism of imipenem by the kidney, increasing the t½ and decreasing the nephrotoxicity of imipenem. Imipenem exhibits activity against Gram-negative bacilli at least equal to that of the third-generation cephalosporins (including anti-Pseudomonas potency equal to that of ceftazidime); against Gram-positive cocci similar to that of oxacillin, nafcillin, and cefazolin; and against anaerobic bacteria equal to metronidazole and clindamycin. MRSA are resistant to imipenem. Enterococcus faecalis appears susceptible in vitro, but Enterococcus faecium usually is resistant, and imipenem should not be regarded as effective therapy for serious infections caused by enterococci. Among nonfermentative Gram-negative bacilli associated with nosocomial infections, S. maltophilia, Burkholderia cepacia, and Flavobacterium spp usually are resistant to imipenem. Resistance to imipenem arises infrequently (most commonly with P. aeruginosa) during therapy, usually via alteration in porin channels in the bacterial cell outer membrane, resulting in diminished intracellular concentrations of the drug. The usual dosage of imipenem/cilastatin is 2 g per day in four divided doses, with up to 4 g per day in life-threatening infections by less susceptible organisms (e.g., P. aeruginosa). Dosage adjustment (see Table 73.2) is necessary for patients with renal dysfunction because serum concentration-related myoclonus and seizures can occur. Treatment of highly resistant Gram-negative bacilli (e.g., P. aeruginosa, E. cloacae, and Acinetobacter spp) with imipenem may involve initial coadministration of a second agent, such as an aminoglycoside.

Adverse reactions to imipenem include rash and fever. The frequency of cross-reactivity with other classes of β-lactams is estimated to be approximately that observed with penicillins and cephalosporins. Risk of seizures can be minimized by adjustment of dosing in the elderly and in patients with reduced renal function; usage should be avoided when possible in patients with a history of seizures or central nervous system (CNS) lesions.

Meropenem and ertapenem are broad-spectrum carbapenem antibiotics similar to imipenem. Meropenem is more active against Gram-negative rods, including Pseudomonas spp, and slightly less active against Gram-positive cocci, including S. aureus. Ertapenem is not active against Pseudomonas spp or Enterococcus spp but has activity against extended-spectrum β-lactamase (ESBL) producing Klebsiella. The
standard dosing for ertapenem is 1 g IV every 24 hours and for meropenem 1 g IV every 8 hours (see Table 73.2). Meropenem and ertapenem are excreted via the kidney but, in contrast to imipenem, their renal metabolism is negligible and cilastatin is not coadministered. Meropenem and ertapenem are less likely than imipenem to cause seizures.

Doripenem is a novel carbapenem with a broad spectrum of activity against Gram-positive pathogens, anaerobes, and Gram-negative bacteria, including *P. aeruginosa*. Doripenem exhibits rapid bactericidal activity with two- to fourfold lower MIC values for Gram-negative bacteria, compared with other carbapenems. It has significant in vitro activity against *Enterobacteriaceae* (including ESBL+ strains), *P. aeruginosa*, *Acinetobacter* spp, and *B. fragilis*. Doripenem is dosed at 500 mg IV every 8 hours; dose and/or interval adjustment is required based on creatinine clearance (see Table 73.2). Low risk of seizures has been demonstrated in clinical studies [21].
AZTREONAM

Aztreonam is a monobactam, differing from penicillins and cephalosporins in that it has a monocyclic rather than a bicyclic nucleus, granting aztreonam little cross-allergenicity with other β-lactams. Although skin rashes occur occasionally with this drug, aztreonam has been given safely to patients with immediate hypersensitivity-type reactions (anaphylaxis, urticaria) to penicillins or cephalosporins. Aztreonam has no activity against Gram-positive or anaerobic bacteria. Against most facultative aerobic Gram-negative bacilli, aztreonam exhibits a spectrum and potency much like that of third-generation cephalosporins, including activity against some strains of Pseudomonas spp. The usual dosage of aztreonam is 1 to 2 g IV every 6 to 8 hours. Aztreonam is cleared by the kidneys, and dosage must be reduced in patients with renal insufficiency.
AMINOGLYCOSIDES

Aminoglycoside antibiotics are anti-bactericidal agents of value in the treatment of Gram-negative infections in ICU patients [22]. Aminoglycosides in common clinical use for the critically ill patient include gentamicin, tobramycin, and amikacin. Streptomycin occasionally is used for treatment of enterococcal or mycobacterial infections.

Pharmacology

All available aminoglycosides exhibit similar pharmacologic properties: (a) absorption from the gastrointestinal (GI) tract is negligible, and adequate serum levels are obtained only by the IV or intramuscular routes; (b) volume of distribution is similar to that of total volume of extracellular fluid and therefore can be unpredictable under conditions of abnormal extracellular fluid, such as dehydration, third-space losses, congestive heart failure, or ascites; (c) protein binding is minimal; (d) penetration into the cerebrospinal fluid (CSF) is poor even in the presence of meningeal inflammation; (e) drug levels in bronchial secretions are only two thirds of those in serum and are poor in vitreous fluid, prostate, and bile; (f) excretion is predominantly by glomerular filtration, and $t_{1/2}$ of the aminoglycosides in the presence of normal renal function is approximately 2 to 3 hours (longest for amikacin) and is prolonged in patients with renal impairment, approaching 24 hours in those with end-stage renal failure; (g) all aminoglycosides are dialyzable, and greater efficacy of removal occurs with hemodialysis (approximately 60% to 75% cleared in 6 hours) than with peritoneal dialysis; and (h) aminoglycoside activity is reduced under conditions of reduced pH and oxygen tension, such as in purulent, particularly anaerobic, fluids, and tissues [22].

Spectrum of Action and Indications for Therapy

The primary clinical indication for aminoglycoside therapy is serious infection caused by Gram-negative bacilli. Aminoglycosides also are used in combination with a cell wall agent for therapy of enterococcal endocarditis. Another indication is treatment of mycobacterial disease. Although more toxic than penicillins and cephalosporins, aminoglycosides provide the broadest range of potent, bactericidal antibiotic activity against Gram-negative bacilli, particularly when multiply-resistant enteric Gram-negative bacilli (e.g., *Enterobacter* spp)
or nonfermentative Gram-negative organisms such as *Pseudomonas* and *Acinetobacter* spp are considered possible pathogens. Resistance to aminoglycosides generally emerges slowly and infrequently. However, resistance to aminoglycosides has increased dramatically among *Enterococcus* spp, and currently in many hospitals, up to one fourth of isolates are gentamicin-resistant [23]. Some high-level gentamicin-resistant isolates remain susceptible to high levels of streptomycin.

**Gentamicin and Tobramycin**

In many ICUs, gentamicin (and tobramycin) resistance is prevalent among local isolates of Gram-negative bacilli, and amikacin may be preferred in the initial management of Gram-negative bacillary infections, pending results of susceptibility testing. In addition, gentamicin in combination with ampicillin, penicillin, or vancomycin is indicated for treatment of endocarditis due to enterococci or viridans group streptococci and can be used with vancomycin and rifampin for treatment of prosthetic valve endocarditis caused by coagulase-negative staphylococci. Tobramycin is more potent than gentamicin against *P. aeruginosa* in vitro and, along with amikacin, may be effective against gentamicin-resistant strains of this organism. However, the frequency of cross-resistance is unpredictable and may be alarmingly common. In addition, tobramycin is less active than gentamicin against some organisms, such as *Serratia* spp and *Acinetobacter* spp.

**Amikacin**

Amikacin is the semisynthetic aminoglycoside most resistant to aminoglycoside-inactivating enzymes. For most gentamicin-resistant Gram-negative bacilli such as multiresistant ESBL-producing *Klebsiella*, amikacin is the most active aminoglycoside and should be the empiric aminoglycoside of choice in hospitals or ICUs in which gentamicin and tobramycin resistance is prevalent.

**Adverse Reactions**

Unlike β-lactam antibiotics, aminoglycosides are characterized by a narrow therapeutic–toxic ratio, and therapy with these agents can be associated with considerable toxicity. Hypersensitivity reactions such as fever and rash are uncommon and anaphylaxis has been observed rarely. Neuromuscular blockade has been described uncommonly and appears to be of concern only in patients with myasthenia gravis or severe hypocalcemia or those who are receiving neuromuscular blocking agents. Ototoxicity appears to occur with equal frequency (up to 10% of patients)
among the modern aminoglycosides. Vestibular damage has been described more commonly with gentamicin and tobramycin, whereas impairment of auditory acuity seems more common with amikacin [22]. Ototoxicity occurs unpredictably (either early or late in therapy), is related only partially to elevated serum levels, most closely correlates with duration of therapy and total dosage administered, and often is irreversible. Patients expected to receive aminoglycoside therapy for extended duration and who are conscious and communicative should be questioned periodically about symptoms of eighth cranial nerve dysfunction, such as tinnitus, diminished auditory acuity, lightheadedness, and dizziness.

Nephrotoxicity has been reported to occur in 2% to 10% of all patients receiving aminoglycoside therapy and in up to 10% to 25% of critically ill patients. However, renal damage usually is mild and reversible promptly with cessation of therapy. Aminoglycoside-induced nephrotoxicity is related to dose and duration of therapy as well as to serum concentrations, especially elevated trough levels. It occurs more commonly among elderly patients, those with preexisting renal disease, those with diminished tissue perfusion caused by cardiogenic or peripheral vascular factors, and patients receiving other nephrotoxic agents. The most useful laboratory tests available to reduce and detect aminoglycoside nephrotoxicity are the serum creatinine levels and determinations of trough serum aminoglycoside concentrations.

Therapy and Determination of Serum Levels

Recommended dosage schedules and desired serum concentrations for the aminoglycosides are shown in Table 73.3. The use of the once-daily dosing method for aminoglycosides (see Table 73.3) may reduce nephrotoxicity and enhance efficacy against Gram-negative bacilli [24]. These agents induce a postantibiotic effect, and hence are suited for less frequent dosing. Postantibiotic effect is uncertain for Gram-positive bacteria, and the desired peak and trough levels are lower when aminoglycosides are employed for synergistic activity against Gram-positive pathogens. For patients with impaired renal function, serum concentrations (and serum creatinine and blood urea nitrogen values) should be monitored to ensure safe and effective concentrations. Trough concentrations should be monitored frequently (and dosage/frequency adjusted accordingly) in patients with fluctuating cardiovascular function/fluid volumes or renal function and in those who are anticipated to receive prolonged therapy. Trough serum concentrations should be
less than 1 μg per mL (or undetectable) when large doses are given at intervals of 24 hours or greater. In patients undergoing hemodialysis, it can be estimated that approximately two thirds to three fourths of a dose (i.e., 1 mg per kg gentamicin or tobramycin or 5 mg per kg amikacin) is required at the end of each hemodialysis session, and serum concentrations (trough before dialysis, peak after supplemental dose given) should be monitored. In patients undergoing peritoneal dialysis, instillation of the aminoglycoside into the dialysate at a therapeutic concentration (i.e., 4 μg per mL = 4 mg per L for gentamicin and tobramycin and 20 μg per mL = 20 mg per L for amikacin) eliminates a serum-dialysis concentration gradient and minimizes loss of drug through dialysis.

</table>

Creatinine clearance; for women, multiply the result by 0.85.

a Lower concentrations are desired when using aminoglycosides for treatment of gram-positive infections.

b Serum for peak levels should be drawn 30 min after a 30-min infusion, and trough levels should be obtained within the 30 min before the next dose.

c Patient exclusions—age <12 y, pregnancy, burns >20% body surface area, ascites, dialysis, endocarditis, creatinine clearance <60 mL/min.

d NA—with once-daily dosing, peak concentrations are high transiently and measurement of peaks is not applicable.
Fluoroquinolones are broad-spectrum agents that exert their antimicrobial activity by inhibiting deoxyribonucleic acid (DNA) synthesis via binding to two enzymes, bacterial DNA gyrase and topoisomerase IV, enzymes that induce superhelical twists into double-stranded bacterial DNA. Fluoroquinolones broadly in use include ciprofloxacin, levofloxacin, and moxifloxacin. These agents are active and generally bactericidal against susceptible enteric Gram-negative bacilli (including enteric pathogens such as Salmonella spp and Shigella spp), H. influenzae. Resistance to these agents is increasing among Gram-negative bacteria such as P. aeruginosa, Acinetobacter spp, and Aeromonas hydrophila; non–lactose-fermenting Gram-negative bacilli, such as B. cepacia, Pseudomonas fluorescens, and S. maltophilia, often are resistant to the quinolones. Of the quinolones, ciprofloxacin has greatest potency against P. aeruginosa. Activity of quinolones against aerobic Gram-positive cocci is variable, and activity against methicillin-susceptible S. aureus and coagulase-negative staphylococci has diminished; MRSA commonly are resistant [25]. Although, in general, streptococci (particularly S. pneumoniae, Streptococcus pyogenes) and enterococci exhibit poor susceptibility to older quinolones (i.e., ciprofloxacin), moxifloxacin and levofloxacin are considered efficacious in treatment of pneumococcal pneumonia. Moxifloxacin has in vitro activity against B. fragilis, but there is little clinical experience with its use against this pathogen. Quinolones have activity against mycobacteria, including Mycobacterium tuberculosis, Mycobacterium kansasii, and Mycobacterium fortuitum, but susceptibility results should be used to guide therapy. Levofloxacin and moxifloxacin are more active than ciprofloxacin against Mycoplasma spp, Chlamydophila trachomatis, and Ureaplasma urealyticum. All demonstrate activity against Legionella pneumophila. The $t_{1/2}$ of the fluoroquinolones is relatively long (3 to 4 hours for ciprofloxacin and levofloxacin, and 9 to 10 hours for moxifloxacin). Levofloxacin is cleared primarily by the kidneys and requires dosage adjustment for patients with renal insufficiency. Moxifloxacin is cleared by the liver, and dosage adjustments in renal failure are unnecessary. Some hepatic excretion occurs with ciprofloxacin, and major dosage adjustment (50% of dose, 12-hour interval) is required only at creatinine clearance rates of less than 20 mL per minute. The fluoroquinolones are not eliminated by hemodialysis or peritoneal dialysis. Although available oral fluoroquinolone formulations can achieve adequate serum and tissue concentrations to treat infections outside the urinary tract, parenteral therapy is preferred in the acute
management of serious infections in the ICU, as oral absorption may be unreliable due to problems with intestinal motility or perfusion. Ciprofloxacin, moxifloxacin, and levofloxacin are available in IV preparations. GI tract absorption of fluoroquinolones can be impaired by concomitant administration of antacids, sucralfate, and multivitamins containing zinc or iron.

Adverse Reactions

In general, fluoroquinolones are safe and well tolerated. The most common adverse reactions include GI tract symptoms (nausea, vomiting, dyspepsia, abdominal pain, and diarrhea), CNS symptoms (insomnia, restlessness, headache, dizziness, confusion, and, rarely, seizures), tendon rupture, and occasional hypersensitivity reactions (rash, pruritus, and drug fever). Ciprofloxacin increases serum concentrations and potentiates the effects of theophylline, warfarin, and cyclosporine.

Indications

The fluoroquinolones are indicated for the treatment of (a) complicated urinary tract infections involving susceptible Gram-negative bacilli; (b) prostatitis; (c) bacterial pneumonia, especially due to Gram-negative bacilli, H. influenzae, Legionella sp, or high-level penicillin-resistant S. pneumoniae; (d) bacterial diarrhea of diverse etiologies, including traveler’s diarrhea and enteritis due to Shigella, Salmonella, and Campylobacter spp; (e) invasive (malignant) external otitis; (f) intra-abdominal and intrapelvic infections (in combination with anaerobic coverage); (g) outpatient treatment of CAP; and (h) septic shock due to urinary tract infections, in combination with a β-lactam agent. For treating nosocomial pneumonia, it must be remembered that the older fluoroquinolones (e.g., ciprofloxacin) have limited activity against streptococci and no activity against anaerobes, and addition of an agent active against these organisms should be considered. In addition, resistance to fluoroquinolones is becoming increasingly common in S. aureus and among Gram-negative bacilli, especially P. aeruginosa.
Vancomycin is bactericidal at low concentrations against most Gram-positive cocci and bacilli, including *S. aureus* (including MRSA), coagulase-negative staphylococci, *S. pneumoniae* (including drug-resistant strains), viridans group *Streptococcus* spp, *Streptococcus bovis*, *Clostridium* sp, and *Diphtheroid* spp. Although most enterococci are inhibited by low concentrations of vancomycin, bactericidal killing of these organisms requires the addition of an aminoglycoside such as gentamicin or streptomycin. Resistance to vancomycin is an emerging problem, particularly in strains of *E. faecium*. Because of poor absorption from the GI tract and severe pain with intramuscular injection, vancomycin is given IV for the treatment of systemic infections. Oral vancomycin is used only for patients with antibiotic-associated colitis caused by *Clostridium difficile*. In severely ill patients with *C. difficile* infection, oral vancomycin or a combination of oral vancomycin and IV metronidazole is recommended. Vancomycin is excreted primarily by the kidneys. In patients with normal renal function, serum $t_{1/2}$ of IV-administered vancomycin varies from 2.7 to 13.3 hours, and peak and trough serum concentrations are unpredictable. The usual recommended dose for adults with normal renal function is 2 to 3 g per day in divided doses every 8 to 12 hours. The dose should be administered IV over 60 minutes. For complicated infections in seriously ill patients, a loading dose of 25 to 30 mg per kg (based on actual body weight) may be used to achieve target concentration rapidly, followed with 15 to 20 mg/kg/dose every 8 to 12 hours. Nomograms are available to guide vancomycin dosing in patients with varying degrees of renal insufficiency. Serum trough concentrations should be monitored for patients with reduced renal function or unstable hemodynamics; monitoring of peak concentrations usually is not helpful. For pneumonia due to MRSA and meningitis, dosing to achieve higher troughs of 15 to 20 μg per mL should be used. For endocarditis dosing to achieve troughs of 10 to 15 μg per mL are recommended [26].

**Adverse Reactions**

Because there is no cross-reaction with β-lactam allergy, vancomycin is the drug of choice in the therapy of serious Gram-positive infections in patients who are allergic to penicillins and cephalosporins. Vancomycin is associated with hypersensitivity reactions such as rash and fever in approximately 3% to 5% of patients. Rapid IV administration of vancomycin can produce a histamine-associated reaction characterized
by flushing, tingling, pruritus, tachycardia, hypotension, and an erythematous rash over the upper trunk and face. This Red-Person Syndrome is a histamine-release phenomenon, not a manifestation of hypersensitivity, and can be avoided by slow IV administration of the drug (i.e., at a rate no faster than 15 mg per minute or 0.5 g over 60 minutes and 1 g over 60 to 90 minutes) or by pretreatment with an antihistamine. Neutropenia occurs occasionally [27]. Ototoxicity occurs uncommonly in patients who receive vancomycin, usually in association with elevated serum levels (at least 50 μg per mL), and generally is reversible with discontinuation of therapy. Nephrotoxicity occurs rarely in patients who receive vancomycin alone, is usually associated with elevated serum vancomycin levels, and is more common in patients with recent concomitant aminoglycoside administration.
LIPOGLYCOPEPTIDE

First-Generation Lipoglycopeptide

Telavancin, a glycopeptide analog of vancomycin, telavancin, shows promise as alternative treatment for patients with serious infections caused by Gram-positive pathogens [28]. Telavancin exhibits low potential for resistance development and is active against resistant pathogens, including MRSA. Telavancin currently is approved only for treatment of complicated skin and skin structure infections (cSSSIs). Similar to vancomycin, it demonstrates activity in vitro against a variety of Gram-positive pathogens, including but not limited to MRSA and penicillin-resistant S. pneumoniae. Modifications to vancomycin’s structure expanded telavancin’s spectrum of activity in vitro to include organisms such as glycopeptide-intermediate S. aureus (GISA), vancomycin-resistant S. aureus (VRSA), and vancomycin-resistant enterococci (VRE). Dosing at 10 mg/kg/d is recommended for patients with normal renal function. Since telavancin is cleared extensively by the kidneys, dosage adjustments will be required in patients with moderate-to-severe renal impairment. Renal toxicity was reported more frequently with telavancin than with vancomycin in two phase III clinical trials (3% vs. 1%). Potential teratogenicity of this agent must be considered in women who are pregnant or may become pregnant.

Second-Generation Lipoglycopeptide

Oritavancin and dalbavancin are indicated for treatment of acute bacterial skin and skin structure infections caused by susceptible Gram-positive organism including MRSA [29, 30]. Oritavancin and dalbavancin, like other lipoglycopeptides, exert concentration-dependent bactericidal activity by disruption of bacterial membrane integrity, leading to cell death. Oritavancin is used in a single 1,200 mg dose administered IV over 3 hours. Oritavancin is not metabolized and it is extensively distributed into tissues. In patients with mild-to-moderate renal impairment no dosage adjustment is required. Oritavancin as well as dalbavancin has not been studied in patients with severe hepatic impairment. Dalbavancin is infused over 30 minutes as a 2-dose regimen of 1,000 mg IV followed 1 week later by 500 mg. Excretion of dalbavancin is by urine (55%) and by feces (20%).
THERAPY OF ANAEROBIC INFECTIONS

As reviewed previously, excellent efficacy against anaerobes is provided by carbapenems as well as β-lactam/β-lactamase combination agents. Additional agents with anaerobic activity include metronidazole and clindamycin.

Metronidazole

Metronidazole is highly active against obligate anaerobes. Although orally administered metronidazole is absorbed nearly completely, critically ill patients with infections other than *C. difficile*–associated diarrhea should receive therapy by the IV route. Metronidazole is administered at 500 mg (7.5 mg per kg) IV every 8 hours [31]. Metronidazole is metabolized by the liver; no dose adjustment is required in patients with renal insufficiency, but dosages must be reduced in individuals with severe hepatic insufficiency. Penetration into CSF and brain is excellent. Reported serious adverse events include neutropenia, pancreatitis, peripheral neuropathy, and hepatitis. Metallic taste (dysgeusia) occurs commonly, and up to 12% of patients have minor GI tract side effects. A disulfiram-like reaction can occur with concomitant alcohol intake.

Metronidazole is active in vitro against anaerobic Gram-negative bacilli and is probably the most potent agent for treatment of infections caused by *B. fragilis*. Metronidazole must be used in conjunction with an agent active against aerobic organisms in the treatment of intra-abdominal, intrapelvic, and pulmonary infections where aerobic organisms can be expected to be concurrent pathogens. It has become the drug of first choice for treatment of *C. difficile*–associated diarrhea because of limitations on the use of oral vancomycin in an attempt to decrease selective pressure for the emergence of VRE, although oral vancomycin, often with IV metronidazole, is preferred for critically ill patients [31].

Clindamycin

Clindamycin is active in vitro against a wide variety of anaerobic bacteria. It has been used with great success in the treatment of anaerobic infections of the head, neck, and lungs/pleural space. The use of clindamycin in addition to penicillin is recommended in the treatment of necrotizing fasciitis due to β-hemolytic *Streptococcus* spp because of its apparent activity against organisms that are present in very high inoculum [32]. Clindamycin-resistant strains of *B. fragilis* group are becoming more prevalent, with 29% of isolates resistant in 2001 versus
10% in 1988. Usual parenteral therapy with clindamycin for severe infections consists of 600 to 900 mg IV every 8 hours (25 to 40 mg/kg/d). Because clindamycin is metabolized by the liver and excreted in inactive form in bile, no adjustment in dosage is required in patients with renal insufficiency. The most important side effects of clindamycin are gastrointestinal. The incidence of diarrhea during therapy with clindamycin has been reported to range from 3% to 30%. Pseudomembranous colitis due to *C. difficile* has been reported to occur in up to 10% of patients who receive clindamycin [33].
MACROLIDES

The macrolides are bacteriostatic antibiotics that act on the 50 S ribosome subunit. The most common use of macrolides is to treat primary atypical pneumonia due to *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *Legionella* spp; pharyngitis due to *S. pyogenes*; *Bordetella pertussis* infections; enteritis due to *Campylobacter* spp; and eradication of the diphtheria carrier state. Erythromycin is the oldest agent in current use in this class, and now is used rarely, with azithromycin or clarithromycin the preferred agents. Erythromycin is used occasionally in the ICU setting to enhance gut motility.

Azithromycin is available in oral and IV preparations and clarithromycin only in oral form. In addition to sharing the microbiologic spectrum of activity of erythromycin, azithromycin is more active against *C. trachomatis* but is less active than erythromycin or clarithromycin against staphylococci and streptococci. Clarithromycin shares the antimicrobial spectrum of erythromycin but is more active against Gram-positive cocci. Both agents have activity against *Mycobacterium avium-intracellulare* and *Mycobacterium chelonae* and are used prophylactically and therapeutically for disseminated *M. avium* complex infection in patients with advanced human immunodeficiency virus (HIV) disease. These agents are bacteriostatic and not usually used as first-line agents for treatment of Gram-positive infections in the ICU.
OXAZOLIDINONES

First-Generation Oxazolidinones

Linezolid, the first available oxazolidinone antimicrobial, exerts its action by inhibiting the initiation of protein synthesis by stopping assembly of bacterial ribosomes [34]. Linezolid has bacteriostatic activity against MRSA, VRSA, and VRE and is bactericidal against penicillin-resistant S. pneumoniae. It is approved for treatment of nosocomial pneumonia and cSSSIs caused by S. aureus (including MRSA). It is available for IV or oral use at a dosage of 600 mg every 12 hours and has excellent oral bioavailability. Dosage adjustments are not necessary for patients with renal insufficiency. The oxazolidinones have the potential for interaction with monoamine oxidase inhibitors, selective serotonin receptor uptake inhibitors (SSRIs), adrenergic agents used to support blood pressure in the ICU, and foods that contain a high tyramine content, with potential to trigger the serotonin syndrome, which can involve cognitive, autonomic, and somatic manifestations, presenting variously as confusion, agitation, coma, autonomic instability, flushing, low-grade fever, nausea, diarrhea, diaphoresis, myoclonus, rigidity, and rarely myoclonus and death [35]. Reversible thrombocytopenia may occur if treatment is given longer than 14 days. Resistance may develop in enterococci with long-term use and has been reported in S. aureus [36,37].

Second-Generation Oxazolidinones

Tedizolid is approved for treatment of bacterial skin and skin structure infection with susceptible isolates of Gram-positive microorganisms including methicillin-sensitive and methicillin-resistant S.aureus and E. faecalis [38]. Tedizolid is either infused over 1 hour or given orally in a dose of 200 mg every day. Tedizolid is excreted 82% in feces; 18% in urine. No dosage adjustment required for patients with renal or hepatic impairment.

Quinupristin/Dalfopristin

Quinupristin/dalfopristin is a combination of two streptogramin antibiotics used to treat infections due to vancomycin-resistant E. faecium and other Gram-positive bacteria, including S. aureus. This agent is given by the IV route and, due to a high incidence of phlebitis, has to be administered through a central vascular catheter. It has bacteriostatic activity against E. faecium. The dose is 7.5 mg per kg every
8 hours for serious infections and 7.5 mg per kg every 12 hours for skin and skin structure infections. This drug is reserved for patients with difficult-to-treat infections. Quinupristin/dalfopristin has been used for a few patients with meningitis, and CSF concentrations appear to be higher than the MIC for susceptible organisms. Myalgias and arthralgias occur in up to 10% of patients and may limit its use [39].

**Daptomycin**

Daptomycin, a cyclic lipopeptide antimicrobial agent with rapid, concentration-dependent bactericidal activity against aerobic and facultative Gram-positive microorganisms, is active against a range of Gram-positive bacteria, including many multidrug-resistant isolates. Daptomycin is approved for treatment of cSSSIs caused by susceptible strains of *S. aureus* (including MRSA), *S. pyogenes*, and other *Streptococcus* and *Enterococcus* species. The dosage of daptomycin for soft tissue infections is 4 mg per kg every 24 hours by IV infusion given over 30 minutes for patients with a creatinine clearance greater than 30 mL per minute. A dose of 6-8 mg per kg every 24 hours is recommended for bacteremia and right-sided endocarditis caused by susceptible strains of *S. aureus* (including MRSA). In the lung, daptomycin is bound to surfactant, and thus it is not clinically effective for treatment of pneumonia [40]. The drug is excreted primarily via the kidney, with low potential for interference with hepatically metabolized drugs. If the creatinine clearance is less than 30 mL per minute, the dosage interval should be extended to 48 hours. Reported adverse effects include diarrhea, vomiting, sickle-cell crisis, hypersensitivity reactions, dermatitis, myalgias, and creatinine kinase elevations [41,42].

**Tigecycline**

Tigecycline, a minocycline derivative, is the first antibiotic in the glycyccycline class [43]. Tigecycline is one of the few new antimicrobials with activity against Gram-negative bacteria, including multiresistant *Acinetobacter* spp and organisms that produce ESBL. In addition, it is active against Gram positives such as MRSA and enterococci including VRE. Tigecycline is approved treatment of cSSSIs and complicated intra-abdominal infections. Tigecycline is available only for IV administration, given as a 100-mg initial dose, then 50 mg every 12 hours. The most common treatment adverse effects are nausea and vomiting which occur generally during the first 2 days of therapy.
THERAPY OF FUNGAL INFECTIONS

Invasive and disseminated fungal infections are increasingly common in ICU patients, especially those who receive immunosuppressive therapy or broad-spectrum antibiotics; in patients with lymphoreticular malignancies or transplants; and in individuals with advanced HIV disease. Newer antifungals of the triazole class (fluconazole, itraconazole, voriconazole, and posaconazole) and echinocandin class (caspofungin, micafungin, and anidulafungin) have become available for the treatment of systemic mycoses. However, amphotericin B remains important for empiric initial therapy for life-threatening fungal infections when the infecting organism is not yet identified or is resistant to triazoles.

Amphotericin B

Amphotericin B is a polyene antibiotic, insoluble in water, and solubilized by the addition of sodium deoxycholate, forming a colloidal dispersion. Its mechanism of action is due to its binding to ergosterol, a sterol present in the cell membrane of susceptible fungi, resulting in altered membrane permeability and causing leakage of cell components and resultant cell death. Amphotericin B is effective against most species of fungi that are pathogenic in humans [44]. Either amphotericin B deoxycholate or one of the liposomal preparations is the initial drug of choice for empiric therapy of life-threatening, invasive, or systemic fungal infections including mucormycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis and is effective for blastomycosis and extracutaneous sporotrichosis. Although Candida albicans generally is susceptible to amphotericin B, non-albicans species of Candida often are less susceptible, and fluconazole or an echinocandin is the drug of choice once the infecting species is identified and susceptibility is known. Amphotericin B preparations have variable activity against Aspergillus spp, Zygomycetes spp, Scedosporium boydii, Fusarium spp, and dematiaceous fungi. The combination of amphotericin B plus flucytosine is synergistic against Candida spp and Cryptococcus neoformans and is used to treat meningitis due to these fungi.

Amphotericin B for IV administration should be prepared in 5% dextrose because saline solutions result in drug precipitation. The drug is highly protein bound and is distributed into many tissues (liver, spleen,
lung, muscle, kidney, skin, and adrenals); because penetration into CSF is poor, intrathecal/intracisternal administration or the use of triazoles may be necessary for some CNS mycoses. The metabolism of amphotericin B is obscure, but renal and hepatic insufficiency has little effect on serum levels of the drug and hemodialysis does not affect serum levels.

Amphotericin B usually is given by IV infusion once a day over 2 to 6 hours, at a concentration of 0.1 mg per mL. Daily and total doses are adjusted according to the fungal species, sites, and extent of infection and the individual tolerance of the patient. A test dose of 1 mg (in 25 to 100 mL 5% dextrose) is infused over 30 minutes. For patients who are critically ill with apparently rapidly progressive fungal disease, the full daily dose of 0.5 to 1.0 mg per kg can be given immediately following the test dose. For patients who exhibit poor tolerance with the test dose or subsequent increased doses, amphotericin B dosing can be increased in a gradual fashion, with increase in the dosage by 5 to 10 mg per day until the final daily dose is reached. The usual duration of amphotericin B therapy for systemic mycoses is 4 to 12 weeks, to a total dose of 1 to 2 g. For infections caused by less susceptible fungi (e.g., Aspergillus spp, Zygomycetes spp [Mucor], and Coccidioides immitis), treatment warrants daily doses of up to 1.0 to 1.5 mg per kg and a total dose of 2 g. Cryptococcosis can be treated successfully with reduced (0.3 mg/kg/d) dosages of amphotericin B plus flucytosine (150 mg/kg/d orally) for 6 weeks.

Adverse Reactions

Adverse effects of amphotericin B most frequently include infusion-associated constitutional symptoms such as fever, chills, hypotension, and tachypnea, most common and most severe with the first few doses of the drug and during escalation of dosage and can be minimized by increasing daily dosage slowly (if the clinical situation permits) or by pretreatment with acetaminophen, hydrocortisone (25 to 50 mg IV), or meperidine (25 mg IV). Dantrolene (10 mg IV) has been used successfully as an alternative or adjunctive agent in patients with severe rigors [45]. Nephrotoxicity occurs frequently with amphotericin B deoxycholate therapy, and thus patients with renal insufficiency or administration of other nephrotoxic agents should be given one of the lipid preparations. Potassium levels should be monitored closely and supplementation with potassium begun as soon as serum potassium decreases toward the low end of normal range. Mild anemia occurs commonly during amphotericin B therapy, but thrombocytopenia, leukopenia, and severe hepatitis are rare. Alternative lipid preparations of amphotericin B have become available in an attempt to decrease renal toxicity [46]. The lipid formulations are more expensive than
amphotericin B deoxycholate but are advantageous in patients with, or at risk of, renal insufficiency, those on other nephrotoxic medications, or those whose renal function worsens during treatment with amphotericin B. The ability to deliver a higher dose with the lipid complex than with amphotericin B alone has resulted in reports of patients responding to the lipid formulation at high dose (5 to 10 mg per kg) when traditional therapy with amphotericin B had been ineffective.

**Flucytosine**

Flucytosine is an orally administered pyrimidine analog with a narrow spectrum of action, generally used in combination with an amphotericin preparation for therapy of *C. neoformans* and *Candida* meningitis. Most strains of *C. neoformans* and *Candida* spp are susceptible initially, whereas most other fungi that are pathogenic for humans are resistant. The use of combination therapy with flucytosine allows a reduction in dosage and duration (0.3 mg/kg/d for 6 weeks) of amphotericin B in treatment of cryptococcal meningitis and improves efficacy in the treatment of *Candida* meningitis because of its excellent penetration into this site. The drug is cleared by the kidneys, with a serum $t_{1/2}$ of 3 hours in patients with normal renal function and 85 hours in anuric patients. The usual recommended dosage in patients with normal renal function is 150 mg per kg daily in four divided doses; the interval between doses should be doubled (every 12 hours) when the creatinine clearance rate is 20 to 40 mL per minute and quadrupled (every 24 hours) when the creatinine clearance rate is 10 to 20 mL per minute. The serum level of flucytosine should be monitored, particularly in patients with renal impairment, and the dose should be adjusted to maintain a level of 50 to 100 μg per mL. Leukopenia is the most serious complication of flucytosine therapy and occurs most commonly in patients with renal insufficiency and when serum levels exceed 100 μg per mL. GI tract intolerance (nausea, vomiting, anorexia, or diarrhea), hepatitis, and rash occur occasionally.
TRIAZOLES

Fluconazole

Fluconazole is a water-soluble triazole available for IV and oral use and exhibits good activity in vitro against *Candida* spp and *C. neoformans* [47]. As with all the triazoles, its mode of action is mediated through inhibition of ergosterol synthesis. Oral absorption is excellent, resulting in serum levels nearly as high as with IV administration, and is independent of gastric acidity. Fluconazole penetrates well into bodily fluids, including CSF (50% to 90% of serum concentrations) and the eye. Fluconazole has a long (30 hours) $t_{1/2}$; because of its renal clearance, adjustments must be made in dosing in patients with renal impairment. For patients with oropharyngeal or esophageal candidiasis, the usual dosage of fluconazole is 200 mg (oral or IV) on the first day of therapy, followed by 100 mg once a day; therapy is continued until clinical findings resolve and for a total of 2 to 3 weeks. Fluconazole (800 mg loading dose, then 400 mg once daily) is effective in the treatment of systemic or hepatic candidiasis due to susceptible strains of *C. albicans* [48]. Non-albicans species of *Candida* may be less susceptible. For severe systemic mycoses (i.e., coccidioidomycosis, cryptococcosis) or candidemia, the usual daily dosage is 800 mg then 400 mg IV daily. Side effects of fluconazole are relatively minor and uncommon, with GI tract symptoms (nausea) most frequent. Mild, transient elevation of serum transaminase levels occurs occasionally. Fluconazole inhibits the metabolism and potentiates the effects of warfarin, phenytoin, cyclosporine, tacrolimus, and oral hypoglycemic agents.

Itraconazole

Itraconazole, a broad-spectrum triazole antifungal with notable activity against *Aspergillus* spp, *H. capsulatum, C. immitis*, and *Sporothrix schenckii*, is available for IV or oral use. Itraconazole is widely distributed in most tissues but with poor penetration into CSF. Itraconazole has a role in the treatment of sporotrichosis, blastomycosis, histoplasmosis, paracoccidioidomycosis, and chromomycosis and may be of use in treating patients with coccidioidomycosis, cryptococcosis, or aspergillosis who have failed prior therapy with amphotericin B or other azoles. Daily dosage is 200 to 800 mg orally, with the higher doses indicated in patients with CNS infection. Clearance is by hepatic metabolism, and no adjustment of dosage is required in patients with renal failure. Like voriconazole, the IV form of itraconazole includes cyclodextrin to
improve solubility; since cyclodextrin is cleared by the kidney, the IV formulation should not be used if creatinine clearance is less than 30 mL per minute. Itraconazole is well tolerated, with occasional GI tract symptoms (abdominal discomfort, nausea, and diarrhea) or minor elevation of liver chemistry values noted. Itraconazole requires an acidic environment for optimal GI tract absorption. Absorption of the elixir form of the drug is greater than with the capsules, and absorption is better with multiple daily dosing. Itraconazole has only a minimal effect on the synthesis of androgens or cortisol but can produce a picture of mineralocorticoid excess with hypokalemia, edema, and hypertension.

Voriconazole

Voriconazole is a second-generation, broad-spectrum triazole that is a synthetic derivative of fluconazole. Voriconazole is active against strains of \textit{C. krusei} and \textit{C. glabrata} that are inherently fluconazole resistant and against strains of \textit{C. albicans} that have acquired resistance to fluconazole. Voriconazole has a broad activity against many species of \textit{Aspergillus} spp, including \textit{Aspergillus terreus}, which often is resistant to amphotericin B [49]. It is a drug of choice for invasive aspergillosis and refractory infections with \textit{Pseudoallescheria/Scedosporium} and \textit{Fusarium} spp.

Voriconazole is available in oral and IV formulations. The standard loading dose is 6 mg per kg repeated in 12 hours. Patients who weigh more than 40 kg should receive 200 mg every 12 hours for maintenance therapy, and the dosage should be adjusted in patients with mild-to-moderate liver disease. Because the azoles are metabolized by the hepatic cytochrome P450 systems, a variety of drug interactions can occur; however, voriconazole generally is well tolerated. Reported toxicities include elevations in liver enzymes, rash, and, in a third of patients, transient ocular toxicity [50]. The IV form contains cyclodextrin and should be used for short periods (<2 weeks) in patients with renal insufficiency due to accumulation of the metabolites.

Posaconazole

Posaconazole is a second-generation triazole approved for the treatment of oropharyngeal candidiasis, including infections refractory to itraconazole and/or fluconazole [51]. It is approved also as prophylaxis for invasive \textit{Aspergillus} and \textit{Candida} infections in patients older than 13 years who are at high risk of developing fungal infections, such as
hematopoietic stem cell transplant recipients with graft-versus-host disease and neutropenic patients with hematologic malignancies [52,53]. Limited clinical experience suggests efficacy for the treatment of infections due to Zygomycetes and as salvage therapy for patients with invasive aspergillosis and coccidioidomycosis. Posaconazole currently is available only as an oral tablet or suspension and requires administration with food or a nutritional supplement to assure adequate bioavailability. Dose adjustment is not required in the presence of renal or hepatic insufficiency. Although not a substrate of hepatic CYP450 3A4, posaconazole inhibits this enzyme and thus has the potential for significant pharmacokinetic interactions with drugs metabolized by this isoform. Its use in combination with CYP450 substrates that prolong the QTc interval is contraindicated, as is its use with ergot alkaloids. The recommended dosage for posaconazole antifungal prophylaxis is 200 mg (5 mL) three times daily. Recommended therapy of oropharyngeal candidiasis is a loading dose of 200 mg (100 mg twice daily), followed by 100 mg daily for 13 days. Refractory oropharyngeal candidiasis may be treated with 400 mg twice daily, with the duration based on clinical response and the patient’s underlying disease. Experimental treatment of invasive fungal infections with posaconazole at 200 mg orally four times daily and maintenance therapy at 400 mg orally twice daily is based on pharmacokinetic data; however, package labeling does not include this indication. The most common adverse effects associated with the use of posaconazole include headache, fever, nausea, vomiting, and diarrhea.

Isavuconazole

Isavuconazole is indicated for treatment of invasive aspergillosis and mucormycosis. Isavuconazole has activity against most strains of the A. flavus, A. fumigatus, and A. niger as well as invasive mucormycosis caused by Mucorales and fungi such as Rhizopus oryzae and Mucormycetes spp. In a phase 3 clinical trial, isavuconazole demonstrated non-inferiority to voriconazole on the primary endpoint of all-cause mortality at day 42 for the treatment of adult patients with invasive aspergillosis or other filamentous fungi [54]. The overall safety profile for isavuconazole demonstrated similar rates of mortality and non-fatal adverse events as the comparator, voriconazole. Isavuconazole is given at initial dose of 372 mg PO or IV every 8 hours for 6 doses over 48 hours and continues at maintenance dose of 372 mg PO or IV every day. Excretion of isavuconazole is 46.1% by feces; 45.5% by urine. Similar to posaconazole, dose adjustment is not required in the presence of renal and/or hepatic insufficiency. Use of isavuconazole is contraindicated in combination with CYP450 substrates and in patients with familial short QT syndrome.
**ECHINOCANDINS**

**Caspofungin/Micafungin/Anidulafungin**

Caspofungin, micafungin, and anidulafungin are echinocandins, a class of antifungal agents that act on the fungal cell wall by inhibiting glucan synthesis. Echinocandins are available only for IV administration and are active against most species of Candida. Caspofungin can be used for refractory cases of invasive aspergillosis in patients intolerant of voriconazole and amphotericin B. All these agents may be used to treat candidemia with similar success but with fewer side effects than amphotericin B [55]. These agents are highly protein bound and distribute into all major organ sites including the brain; however, concentration in uninfected CSF is low. For caspofungin, the recommended dosage for adults is 70 mg as a loading dose, then 50 mg per day. Dose alteration is recommended in the presence of moderate hepatic insufficiency. Caspofungin is metabolized by the liver, and dose adjustment is required when it is given with other drugs that alter cytochrome P450 activity. In general, caspofungin is well tolerated, with the most frequently reported adverse effects being increased serum transaminases, GI upset, and headaches. Caspofungin is classified as pregnancy category C and should be used during pregnancy only if the potential benefit outweighs the potential fetal risk. These three agents exhibit a fungicidal effect against most Candida spp and have become the drugs of choice for empiric therapy of candidemia in the ICU. However, they are not active against *C. neoformans*. They have a fungistatic effect against *Aspergillus* spp. Micafungin appears comparable to fluconazole as antifungal prophylaxis in patients undergoing hematopoietic stem-cell transplantation [56] and anidulafungin has been used in neutropenic children. Absence of antagonism in combination with other antifungal agents suggests that combination antifungal therapy warrants further study, particularly for severe aspergillosis and candidiasis [57].

---

**Trimethoprim–Sulfamethoxazole**

Trimethoprim–sulfamethoxazole (cotrimoxazole) works through sequential, two-stage inhibition of folate synthesis. It has activity against Gram-positive and Gram-negative bacteria, *Nocardia* spp, and *Pneumocystis jiroveci* (previously known as *P. carinii*). Trimethoprim–
sulfamethoxazole can be used in the therapy of Gram-negative infections in the ICU patient, including those caused by *Enterobacter* spp. The dose for serious bacterial infections is 8 to 10 mg/kg/d (of the trimethoprim component), divided every 6 to 12 hours.

Trimethoprim–sulfamethoxazole is the drug of choice for *Pneumocystis jiroveci* pneumonia [58]. In moderately to severely ill patients, it is administered IV or orally at a dosage of 15 to 20 mg/kg/d of the trimethoprim component in three to four divided doses for a total course of 14 days in non-AIDS patients and at a dosage of 15 mg per kg of the trimethoprim component daily (or 75 mg per kg of the sulfa component daily) for 21 days in patients with AIDS. Failure to obtain satisfactory response in 5 days (7 days in individuals with HIV infection) warrants change to an alternative regimen (see HIV Chapter 76 for *Pneumocystis* pneumonia therapy). Adverse reactions to trimethoprim–sulfamethoxazole occur in approximately 10% to 15% of patients who are uninfected with HIV-1 and in up to two thirds of patients with AIDS. The most common problems are neutropenia, thrombocytopenia, or both (particularly in patients with advanced HIV-1–induced immunodeficiency or receiving zidovudine); rash or fever; nausea or vomiting; and abnormalities of hepatic enzymes.

**Pyrimethamine–Sulfadiazine**

For the treatment of systemic and invasive (including encephalitis) toxoplasmosis in the compromised host, the alternate double-antifolate combination of pyrimethamine–sulfadiazine usually is used. Pyrimethamine is administered orally with a loading dose of 200 mg, then at 75 mg daily (with folinic acid 5 mg daily) together with sulfadiazine orally at 6 g daily in four divided doses. Adverse reactions occur in similar frequency and type as with cotrimoxazole. Alternative therapy for CNS toxoplasmosis is clindamycin (900 mg IV every 6 hours) plus pyrimethamine [59].
As viral infections have become more common and more severe in an era of expanding populations of immunocompromised hosts, several antiviral agents have become available (Table 73.4). Nevertheless, antiviral therapy remains problematic and limited in scope as compared with antibacterial treatments. Antiretroviral therapy is discussed in Chapter 76.

**Acyclovir and Related Compounds**

Acyclovir is a nucleoside analog of guanosine with antiviral activity against herpes viruses, particularly herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV) [60]. Administered as a prodrug, acyclovir requires phosphorylation to a monophosphate form by a virus-generated thymidine kinase and then to a triphosphate form by host cellular enzymes. Because cytomegalovirus (CMV) lacks a thymidine kinase, acyclovir has poor activity against this virus. Acyclovir is available in topical, oral, and IV preparations, with the last route preferred for serious infections in critically ill patients and for milder illnesses in those unable to take medications by mouth. After oral administration, absorption is slow and incomplete, with oral bioavailability of only 15% to 30%. Serum $t_{1/2}$ is 2 to 3 hours in patients with normal renal function. Because 85% of clearance is renal, dosage must be reduced in patients with impaired renal function. Acyclovir is well tolerated. Reversible renal impairment, due to crystalluria, occurs occasionally, usually in patients who are receiving high doses by rapid IV infusion or those who are elderly, dehydrated, or have antecedent renal insufficiency. At high doses, especially IV, neurologic reactions (confusion, delirium, hallucinations, seizures, and tremors) have occurred in approximately 1% of patients.
Occasionally, patients experience nausea, vomiting, or rash. Dosage varies according to the condition under treatment. Intravenous acyclovir at 10 to 12 mg per kg every 8 hours is the drug of choice for HSV encephalitis (for a course of 14 to 21 days), for congenital HSV infection (10 to 14 days), and for VZV infections (chickenpox or shingles) in immunocompromised patients (7 to 10 days). Acyclovir at 5 mg per kg IV every 8 hours is effective against mucocutaneous HSV in immunocompromised patients.

Valacyclovir, a prodrug for acyclovir, is more completely absorbed via the oral route than acyclovir and is hydrolyzed rapidly to acyclovir in the intestinal wall and the liver [61]. In general, it is well tolerated, but thrombocytopenia and hemolytic-uremic syndrome have been reported in immunocompromised patients. Other side effects are similar to those of acyclovir and include encephalopathy, fevers, seizures, and rash. Acyclovir, or valacyclovir, is used prophylactically in patients who are undergoing bone marrow or solid organ transplantation.

Famciclovir, a prodrug for penciclovir, is active against VZV and HSV. Side effects are similar to those of acyclovir. Both of the newer oral agents, famciclovir and valacyclovir, are dosed three times a day orally rather than the five times a day that is needed with acyclovir for VZV infections.

**Ganciclovir**

Ganciclovir is highly active against CMV, in part because of the high concentration of the triphosphorylated form of the drug in infected cells. The most problematic adverse effect is myelosuppression, particularly neutropenia. Other side effects include nausea and vomiting and CNS abnormalities. Ganciclovir is effective in the treatment of disseminated CMV and CMV retinitis, GI tract infection (colitis, esophagitis, and gastritis), and pneumonitis. In bone marrow transplant patients, the drug sometimes is used in combination with CMV hyperimmune globulin IV for the treatment of CMV pneumonitis [62]. Valganciclovir is a prodrug for ganciclovir [63]. It is more completely absorbed from the GI tract, achieving higher serum levels than possible with oral therapy with the parent drug.

Treatment with ganciclovir for AIDS patients with CMV retinitis usually involves induction therapy with 5 mg per kg IV twice a day for 14 to 21 days, followed by maintenance therapy with oral valganciclovir. It is given for 3 weeks or until serum CMV molecular assays are negative for
immunocompromised patient with disseminated CMV infection. Ganciclovir and valganciclovir are cleared by the kidney and dosage adjustments must be made in patients with renal impairment, especially in light of the relationship between drug serum levels and myelosuppression. Valganciclovir is used as prophylaxis or preemptive therapy for CMV in transplant patients.

**Cidofovir**

Cidofovir is a nucleotide analog that is active against herpes viruses, including CMV, HSV, and VZV. It is a prodrug that is converted to cidofovir diphosphate by host cellular enzymes. In contrast to ganciclovir and acyclovir, activation by viral-encoded enzymes is not required, so it may be used to treat CMV infections when the virus is resistant to ganciclovir because of its UL97 mutation.

**Foscarnet**

Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analog that acts by inhibiting viral DNA polymerases of most human herpes viruses (particularly CMV) and reverse transcriptases of human retroviruses (particularly HIV-1) [62]. Foscarnet is effective for the therapy of CMV retinitis for patients with AIDS and has been used alone and in combination with ganciclovir to treat ganciclovir-resistant CMV of immunocompromised patients (especially transplant recipients). Foscarnet is associated with a significant (25%) incidence of nephrotoxicity. Therapy involves IV administration at a dosage of 60 mg per kg three times a day for induction and at 90 to 120 mg per kg once a day for maintenance therapy. Clearance is by renal excretion, and dosage adjustment is required in patients with renal impairment. Nonrenal adverse effects include nausea, vomiting, anemia, seizures, and metabolic abnormalities (hyperphosphatemia and hypophosphatemia, hypercalcemia and hypocalcemia, hypokalemia, and hypomagnesemia).

**Anti-Influenza Agents**

Amantadine and rimantadine are oral antiviral compounds that inhibit influenza A, and zanamivir, oseltamivir, and peramivir are neuraminidase inhibitors that inhibit both influenza A and B viruses. If initiated within 48 hours of the onset of symptoms, all four agents may reduce the intensity of influenza infection in patients infected with susceptible viruses [45,64]. For patients who are immunocompromised or who have ongoing viral replication and progressive symptoms, therapy after 48 hours may also be beneficial, although supporting data are not available. Zanamivir is given by the inhaled route and oseltamivir by the
oral route. The dose of oseltamivir is 100 mg per day and for zanamivir 20 mg by inhalation daily. Peramivir is given intravenously as a single dose of 600 mg. Resistance to the antiviral agents has occurred in influenza viruses, and clinicians need to be aware of the susceptibility of prevailing influenza strains in their communities to appropriately choose an agent for use in their ICUs.

This chapter covers several infections of low incidence and high mortality, a combination of factors that challenges the physician to recognize a life-threatening disease he or she may never have seen before and institute appropriate therapy promptly. To assist in this challenge, as these diseases are discussed, key historical points and clinical clues will be emphasized.

The critically ill febrile patient should undergo a thorough history and physical examination. Family members may need to be interviewed if the patient is too ill to participate fully in the history. Key points of the exposure history include travel, employment, hobbies, and exposure to pets, wildlife, and livestock. This portion of the interview will yield better results if it is carried out in a slow-paced conversational manner, allowing the patient or family member to chat a bit. It is less focused than a standard social history and review of symptoms, owing to the heterogeneous nature of the exposures being sought. A complete physical
examination should be performed. In assessing vital signs, one must evaluate hypothermia (temperature less than 36°C) in the same light as fever (temperature higher than 38°C). Laboratory studies should include a complete blood count with platelet and differential counts; prothrombin and partial thromboplastin times; electrolytes, including calcium and magnesium; blood glucose; renal and liver functions; two sets of blood cultures, urine for culture and urinalysis; and a chest radiograph. If a serious infection is under diagnostic consideration, the hematology laboratory should supplement the automated differential leukocyte count with a manual differential count by microscopic examination of the peripheral blood film. This may require a specific request from the physician, especially if the total leukocyte count falls within the normal range.

TOXIC SHOCK SYNDROMES

There are two toxic shock syndromes (TSSs) commonly recognized, one caused by *Staphylococcus aureus* and the other caused by *Streptococcus pyogenes* (group A streptococcus). To further complicate this picture, it has recently been reported that group C and group G streptococci may occasionally cause TSS [1]. In addition, *Clostridium sordellii* has been reported to cause a similar, but clinically distinct, TSS in obstetric patients, injection drug users, and recipients of musculoskeletal tissue allografts. Each of these three syndromes are discussed in the subsequent sections.

**Staphylococcal Toxic Shock Syndrome**

Staphylococcal TSS was first described in 1978 [2], and gained notoriety in the early 1980s when menstrual-associated cases struck large numbers of young women [3]. It is a multisystem disease characterized by acute onset of high fever, hypotension, diffuse macular rash, severe myalgia, vomiting, diarrhea, headache, and nonfocal neurologic abnormalities. The primary focus of staphylococcal infection may be mucosal, typically vaginal, associated with tampon or diaphragm use, or a wound. Currently, there are four well-recognized forms of staphylococcal TSS: menstrual [3], postsurgical [4], influenza associated [5], and recalcitrant erythematous desquamating syndrome in acquired immunodeficiency syndrome [6].

**Etiology**

Staphylococcal TSS is a toxin-mediated illness caused by *S. aureus*
strains that produce superantigens (SAgs). Menstrual-associated TSS is almost always caused by a strain that carries the SAg TSS toxin 1 (TSST-1), which is able to cross intact mucous membranes. Nonmenstrual TSS may be caused by any of 15 described SAgs, but is most commonly associated with TSST-1, staphylococcal enterotoxin B, or staphylococcal enterotoxin C [7]. Staphylococcal enterotoxins B and C are not absorbed across mucous membranes, but can cause TSS in cases of staphylococcal infection of wounds. There are rare case reports of staphylococcal TSS associated with nosocomial strains of methicillin-resistant Staphylococcus aureus (MRSA) [8]. MRSA strains producing TSST-1 have been implicated in the development of a related disease, neonatal TSS-like exanthematous disease (NTED), first described as part of an epidemic in Japanese neonatal intensive care units in the early 2000s, with only isolated case reports in Europe since that time [9–11]. TSS has not been a feature of the epidemic of the community-associated MRSA strain, USA300, nor was TSST-1 identified in a large collection of USA300 isolates [12].

Pathogenesis

In TSS, bacterial toxins function as SAgs. Conventional antigens presented in the context of major histocompatibility molecules on antigen-presenting cells (APCs) must be processed by the APC and recognized by multiple elements of the T-cell receptor (TCR). In contrast, SAgs do not require processing by an APC but instead bind directly to the TCR to activate T cells. Expansion of T-cell populations expressing particular TCR Vβ chains results in massive release of proinflammatory cytokines, such as γ-interferon, tumor necrosis factor α (TNF-α), interleukin 1β (IL-1β), and interleukin-2 (IL-2), leading to a capillary leak syndrome [7]. The absence of preexisting antibody to the pertinent bacterial toxin is a critical host factor of TSS. Among cases of menstruation-associated TSS, 90% do not have preexisting antibody to TSST-1. In contrast, more than 90% of healthy persons older than 25 years of age have antibody to TSST-1. It is also hypothesized that a lack of antibody to TSST-1 in pregnant women may contribute to the development of NTED [10]. Recently, it has been postulated that an altered vaginal microbiome may contribute to the hyperproduction of TSST-1 by commensal S. aureus organisms and present a risk factor for the TSS [13].

Diagnosis

Clinical Features. The classic case profile is a young (15 to 25 years old), menstruating female. However, any staphylococcal infection can
predispose to tss, including surgical wound infections, furuncles, and abscesses. Postpartum cases can occur after vaginal or cesarean delivery. Nasal reconstructive surgery carries an especially high risk of tss. Cases may also occur after nasal packing for epistaxis.

The typical presentation is one of high fever, rash, and confusion. There may be a prodromal period of 2 to 3 days, consisting of malaise, myalgia, and chills. Patients are listless, but focal neurologic findings are not seen. Examination of patients with menstruation-associated TSS reveals vaginal hyperemia and exudate that yields *S. aureus* on culture. In nonmenstrual cases, a careful examination usually reveals a focus of staphylococcal infection. It is important to note that this focus may be subtle, with only serous drainage [4]. This is a toxin-mediated disease, and the local appearance is not one of intense purulence. Drainage of local infections is essential to a favorable outcome.

**Laboratory Findings.** Leukocytosis with marked left shift, thrombocytopenia, azotemia, sterile pyuria, and elevated transaminases are common, although nonspecific findings. Cultures of blood and cerebrospinal fluid (CSF) are usually sterile. Cultures of the local site of infection are usually, but not invariably, positive for *S. aureus*.

**Differential Diagnosis.** Streptococcal scarlet fever, measles, leptospirosis, Rocky Mountain spotted fever (RMSF), Stevens–Johnson syndrome, and Kawasaki disease can mimic TSS. Multiorgan involvement is usually absent in streptococcal scarlet fever, and the primary focus yields *S. pyogenes*. Exclusion of measles, leptospirosis, ehrlichiosis, and RMSF requires a careful history for potential exposures and serologic testing. Stevens–Johnson syndrome is characterized by target lesions and is commonly associated with exposure to medications. Kawasaki disease is characterized by fever and rash without multisystem involvement, is most commonly seen in children younger than 6 years of age, and is associated with thrombocytopathy rather than thrombocytopenia.

The US Centers for Disease Control and Prevention (CDC) case definition of nonstreptococcal TSS consists of both clinical and laboratory criteria, as outlined in Table 74.1 [14]. A confirmed case meets the laboratory criteria and all five clinical criteria; a probable case meets the laboratory criteria and four of the five clinical criteria. The CDC case definition is useful for surveillance purposes, but it identifies the most severe cases and may underestimate the true burden of disease. TSS should be empirically treated when there is a clinical suspicion, even if
not all of the clinical criteria are met.

### TABLE 74.1 CDC Case Definition for Nonstreptococcal Toxic Shock Syndrome

**Clinical criteria:**
- Fever ≥102°F or ≥38.9°C
- Diffuse macular erythroderma
- Desquamation (unless death occurs before the onset of desquamation)
- Hypotension (systolic blood pressure ≤ 90 mm Hg for adults or less than fifth percentile by age for children aged less than 16 y)
- Involvement of three or more organ systems

**Laboratory criteria (if obtained):**
- Negative blood and cerebrospinal fluid cultures for another pathogen (blood cultures may be positive for *Staphylococcus aureus*)
- Negative serologies for Rocky Mountain Spotted Fever, leptospirosis, and measles

A confirmed case meets the laboratory criteria and all five clinical criteria; a probable case meets the laboratory criteria and four of the five clinical criteria.

CDC, Centers for Disease Control and Prevention.

**Treatment**

The primary intervention consists of fluid resuscitation and supportive care. Any focus of staphylococcal infection must be drained. For women, a vaginal examination must be performed as soon as the patient is stabilized, and any foreign bodies (such as tampon or diaphragm) should be removed. After cultures of the local site and the blood are obtained, antistaphylococcal therapy should be administered intravenously.

Empiric antibacterial therapy for the critically ill patient should include an agent that is active against 100% of suspected pathogens, if feasible. At this time, the antibiotic that is most likely to cover all *S. aureus* isolates is vancomycin. There is in vitro evidence that clindamycin [15] and linezolid [16] inhibit staphylococcal toxin production, whereas β-lactam agents increase TSST-1 in culture supernatants, probably because of cell lysis—
releasing toxin [17]. One retrospective study showed improved outcomes for children with TSS who received therapy with clindamycin or erythromycin in the first 48 hours [18]. Initial empiric treatment for TSS when the pathogen has not yet been identified should consist of vancomycin combined with clindamycin. If methicillin-susceptible *S. aureus* is isolated, the vancomycin should be switched to nafcillin or oxacillin, and after 48 hours the clindamycin can be discontinued. First-generation cephalosporins (cefazolin) may be substituted for an antistaphylococcal penicillin in patients with a history of non–life-threatening allergy to penicillins.

Intravenous immunoglobulin (IVIG) may be a useful adjunctive therapy. Higher doses of IVIG may be required for staphylococcal TSS than for streptococcal TSS [19].

**Outcomes**

The mortality of menstrual staphylococcal TSS is 3%, and two to three times higher in nonmenstrual-associated cases. Poor outcomes are associated with prolonged and refractory hypovolemic shock, acute respiratory distress syndrome, acute renal failure, electrolyte and acid–base imbalances, cardiac dysrhythmia, and disseminated intravascular coagulation (DIC) with thrombocytopenia.

Staphylococcal TSS may recur among patients with menstrual or nonmenstrual disease [20,21]. Recurrence is associated with continued use of tampons and absence of antistaphylococcal therapy for the initial episode.

**Streptococcal Toxic Shock Syndrome**

The clinical presentation and pathophysiology of streptococcal TSS are similar to staphylococcal TSS with a few notable differences: bacteremia is commonly seen, rash is less common, and mortality is markedly higher (30% to 70%) [7].

Like staphylococcal TSS, streptococcal TSS is a toxin-mediated disease. Streptococcal toxins that function as SAgs are streptococcal pyrogenic exotoxin A (SPE A) and streptococcal pyrogenic exotoxin B (SPE B). In addition, M-protein, a classic streptococcal virulence factor, may be released from the cell surface, bind to fibrinogen, and form large aggregates that activate intravascular polymorphonuclear leukocytes, leading to a vascular leak syndrome [22]. Blood cultures are usually positive for patients with streptococcal TSS. Underlying infections are varied and include cellulitis, necrotizing fasciitis, postpartum myometritis, surgical wound infection, and, occasionally, pharyngitis [23]. Diagnosis is made by gram stain and culture of blood and other
bodily fluids.

Treatment is similar to that for staphylococcal TSS in that supportive care, including fluids, vasopressors, and ventilatory assistance, should be administered as needed, and surgical drainage of pyogenic sites is imperative. For confirmed streptococcal TSS, the antibiotic of choice is intravenous penicillin. For those who are intolerant to penicillin, other suitable agents are cephalosporins and vancomycin. Until the bacteriologic diagnosis is confirmed by culture, staphylococcal coverage should be included in the antibiotic regimen. Clindamycin is also very active against *S. pyogenes*. In an animal model of streptococcal myositis, clindamycin was more effective than penicillin [24]. This may be owing to greater activity against high burdens of organisms (inoculum effect). An alternative explanation is that inhibition of protein synthesis blocks toxin production by the pathogen and reduces TNF production by the host [25]. A case–control study has shown improved outcomes among children with invasive *S. pyogenes* infections whose therapy included clindamycin or erythromycin in the first 24 hours [18]. Another observational study of patients with invasive *S. pyogenes* infection showed lower mortality associated with clindamycin use, despite higher severity of illness. Clindamycin is, therefore, often recommended to be used in combination with a β-lactam or other cell-wall active agent. The usual adult dose of clindamycin in this setting is 900 mg every 8 hours. Adjunctive therapy of streptococcal TSS with IVIG is recommended by many experts, based on retrospective and observational studies employing doses ranging from 400 to 2 g per kg for variable durations [26–29]. A randomized controlled trial was attempted but halted prior to completion, and it showed a trend toward improved survival in the treatment group [30]. In that trial, the dose of IVIG was 1 g per kg on day 1 and 0.5 g per kg on days 2 and 3.

Outbreaks of infections caused by *S. pyogenes* have previously been reported, and a recent surveillance study noted an increased incidence of invasive *S. pyogenes* infection in household contacts of index cases [28]. However, cases of invasive *S. pyogenes* infections among contacts of index cases remain rare overall. The use of antibiotic prophylaxis for household contacts has not been studied. Although one may consider offering chemoprophylaxis to household contacts with underlying conditions who are at increased risk of sporadic *S. pyogenes* infection or are at increased risk of mortality as a result of this infection (age ≥ 65 or other immunosuppression), its routine use is currently not recommended [31]. Infection control measures in the hospital should include droplet
precautions for the first 24 hours after the initiation of appropriate antimicrobial therapy if pharyngitis and/or pneumonia are possible etiologies; otherwise, standard precautions are sufficient [32].

C. Sordellii Toxic Shock Syndrome

C. sordellii is an anaerobic, gram-positive spore-forming bacillus that has been an occasional cause of obstetric infections for many years [33]. Recently, there have been reports of a TSS caused by this pathogen in association with surgical and medical abortion [33–35], subcutaneous injection of black-tar heroin [36], and musculoskeletal tissue allografts [37]. The distinctive features of this syndrome are hypothermia, and profound hemoconcentration and leukemoid reaction. In one review of C. sordellii cases, a marked leukocytosis was highly predictive of death [38]. Management consists of supportive care, including aggressive volume resuscitation, drainage of purulent foci, and broad-spectrum antibacterial therapy, to include anaerobic organisms. Antitoxin therapy is of theoretic interest, but clinically unproven.
MENINGOCOCCEMIA

The CDC estimated that between 800 and 1,200 cases of invasive meningococcal disease occurred each year during the years 2005 to 2011 in the United States, which represents a decline in incidence since a peak during the late 1990s [39,40]. This section covers Neisseria meningitidis bacteremia. Meningitis is covered in Chapter 81. Although infants are at highest risk for meningococcal disease, case rates also rise in the early teenage years, and 32% of cases occur among persons aged 30 years or older [40]. There are five serogroups, A, B, C, Y, and W-135. In the United States, serogroups B, C, and Y cause 93% of cases, with each representing about one-third of cases. Serogroup B disease is more common among infants. Disease rates vary seasonally, with the lowest rates in the summer and early autumn months [40]. Despite overall decrease in incidence in the United States, recent outbreaks have been reported among men who have sex with men in New York City, Los Angeles, and Chicago [41–44].

Pathophysiology

_N. meningitidis_ colonizes the nasopharynx in normal individuals by adherence to epithelial cells via pili and other adhesion factors. For the majority of individuals, it never causes disease. Invasive disease has been associated with a variety of factors, including antecedent viral infection, exposure to passive smoking, and inhalation of dry, dusty air [45]. Specific antibody and the complement system are key protective components of the host immune system. Deficiency of components of the complement system because of genetic defects or underlying disease predisposes to invasive meningococcal disease [46]. When bacteria invade the bloodstream, endotoxin activates the host immune system and proinflammatory cytokines cause a vascular leak syndrome. The endothelial thrombomodulin–endothelial protein C receptor pathway is downregulated, leading to thrombosis and purpura fulminans [47]. Profound vasoconstriction leads to peripheral ischemia and gangrene [45], and depression of myocardial contractility by cytokines contributes to shock.

Diagnosis

Clinical Manifestations

Few disease states are as impressive as full-blown meningococcal sepsis.
The challenge is early recognition, and intervention before irreversible damage occurs. Early in the course of meningococcal sepsis, nonspecific symptoms and signs are the only manifestations. Fever, malaise, myalgias, vomiting, tachypnea, and tachycardia are typical. The rash begins as an erythema, progressing to the characteristic petechiae and purpura only later in the course of disease. As the disease progresses, it evolves to septic shock, with hypotension, poor peripheral perfusion, impaired mentation, and anuria or oliguria. Other manifestations include hemorrhage, cardiac failure, acute renal failure, and thrombocytopenia with or without DIC [48]. Other, less common complications of meningococcal sepsis include adrenal hemorrhage and failure (Waterhouse–Friderichsen syndrome), chronic renal failure necessitating hemodialysis, cutaneous necrosis with sloughing requiring skin grafting, extremity gangrene requiring subsequent amputation, and often several surgical revisions, septic arthritis, endophthalmitis, and pericarditis. Mortality remains high, despite antibiotics and intensive care; 20% to 50% of children who develop shock from meningococcal sepsis die. Transfer to a specialist unit is associated with a marked reduction of mortality [49].

Laboratory Findings

Leukocytosis or leukopenia, with a shift to immature forms, and thrombocytopenia are typical. There may be laboratory evidence of DIC. Chemistries may demonstrate acidemia, hypoglycemia, decreased cortisol levels, and elevated blood urea nitrogen and creatinine. Diagnosis is confirmed by isolation of *N. meningitidis* from cultures of blood or other normally sterile body fluids. If the diagnosis of meningococcal sepsis is clinically apparent, some experts caution against performing a lumbar puncture for CSF culture because of concerns for brain herniation or clinical deterioration related to positioning the patient for the procedure. Latex agglutination and polymerase chain reaction (PCR) assays provide increased sensitivity [50].

Differential Diagnosis

Purpura fulminans is characteristic of meningococcemia, but may also be caused by *Streptococcus pneumoniae* or *Haemophilus influenzae* type B. Other infections that may mimic meningococcemia are fulminating *S. aureus* sepsis, *S. pyogenes* bacteremia, gram-negative sepsis, RMSF, vasculitis, thrombotic thrombocytopenic purpura, Henoch–Schonlein
purpura, and any febrile illness of a patient with thrombocytopenia.

Therapy

Third-generation cephalosporins are the treatment of choice for meningococcemia owing to reports of penicillin resistance [51]. Ceftriaxone, 4 g intravenously daily in one or two divided doses or cefotaxime 8 to 12 g intravenously daily in four to six divided doses, should be administered to adults with suspected meningococcal disease. There is limited clinical experience with alternative antibacterial agents for patients with a history of cephalosporin allergy. Based on in vitro susceptibility data, options include meropenem and chloramphenicol [51,52]. Fluoroquinolones may be useful for postpubertal persons, but rare cases of fluoroquinolone resistance have been reported [53].

Patients should be admitted to an intensive care unit and placed in respiratory isolation until 24 hours of appropriate antibiotic therapy has been administered. Supportive care is critical to a favorable outcome. Surgical intervention may be indicated for necrotic skin lesions and gangrenous limbs. Early fasciotomy appears to limit the extent of amputation that is ultimately required [54]. Adrenal insufficiency may occur; in hypotensive patients, corticosteroids should be administered pending return of results of cosyntropin stimulation test. Use of plasmapheresis has been reported in uncontrolled series [55,56].

Prophylaxis

The CDC recommends chemoprophylaxis after exposure to people with \textit{N. meningitidis} infection for household, day care, and other close contacts; for people in close contact with infected respiratory secretions, such as those performing mouth-to-mouth resuscitation or endotracheal intubation, and for travelers in contact with respiratory secretions of, or seated next to, an index case for 8 hours or more [39]. The agents recommended for chemoprophylaxis are rifampin (600 mg orally for adults, 10 mg per kg orally for children) given every 12 hours for four doses; ciprofloxacin 500 mg orally once, for adults; or ceftriaxone, 125 mg intramuscularly in children younger than 15 years of age or 250 mg intramuscularly in people aged 15 years or older [39]. Resistance to ciprofloxacin, which has been widely used for prophylaxis, was reported among several cases of meningococcal infection in North Dakota and Minnesota between 2007 and 2008, leading to a recommendation to use alternative agents for prophylaxis in those areas, either rifampin, ceftriaxone, or azithromycin 500 mg orally once [39,57]. Since that time, two additional isolates of ciprofloxacin-resistant \textit{N. meningitidis} have been identified in the United States through susceptibility testing of isolates previously collected by an active population-based surveillance
system operating in 10 states or metropolitan areas, although detection of these strains may be limited because susceptibility testing is not routinely done in the United States [58]. Nevertheless, this same analysis of 466 N. meningitidis isolates collected in the years 2004, 2008, 2010, and 2011 revealed no instances of ceftriaxone or azithromycin resistance, and rare isolates with rifampin resistance [58]. Routine chemoprophylaxis is recommended for medical staff only if they had managed an airway or were exposed to respiratory secretions before the institution of antibiotic therapy. When indicated, postexposure prophylaxis should be given as soon as possible, although it is likely not useful if given greater than 14 days after exposure [39].

Immunization with the tetravalent vaccine MenACWY is indicated for the following populations: children at their 11- to 12-year-old preadolescent health care visit, college freshmen living in dormitories, travelers to areas where N. meningitidis is epidemic or hyperendemic, microbiologists with frequent exposure to N. meningitidis, military recruits, those at risk during an outbreak (such as school or dormitory mates), and those with increased susceptibility (e.g., persons with complement deficiencies or asplenia) [39]. Meningococcal serogroup B (MenB) vaccines have recently been made available and are now recommended for a subset of populations who are also eligible to receive MenACWY (persons with complement deficiencies or asplenia, microbiologists routinely exposed to N. meningitidis, and persons at risk because of an outbreak of serogroup B meningococcal disease; MenB vaccines are not licensed for use in children younger than 10 years of age [59].
OVERWHELMING POSTSPLENECTOMY INFECTION

Overwhelming postsplenectomy sepsis is a catastrophic illness with high morbidity and mortality among patients who have undergone splenectomy or who have severe splenic dysfunction. The spleen provides three major functions for protection from infection. It acts as a mechanical filter for infected or senescent erythrocytes; it participates in the production of soluble immune factors, including immunoglobulins and tuftsin, and it provides a site for components of the cellular immune system to act in proximity to one another [60].

Splenic function may be lost owing to surgical removal, irradiation, several disease processes, and therapies [61], including sickle cell anemia, systemic lupus erythematosus, celiac disease, liver disease, acute alcoholism, high-dose corticosteroid therapy, splenic irradiation [62], and bone marrow transplantation. Normal aging has also been associated with a decrease in splenic function [63].

Splenectomy was the accepted procedure for splenic trauma for centuries, owing to the belief that it served no important physiologic function, repair of trauma was difficult because of the friable nature of the organ, and expected high mortality of attempted conservative management. This prevailing wisdom was challenged in the 1970s, and, currently, splenic salvage is reported in 90% of cases of splenic rupture [64]. Splenic salvage in the trauma setting is associated with marked reductions in the risk of infection during the acute hospitalization, including surgical site infections and pneumonia [65]. Implantation of splenic fragments into the peritoneum has been performed in an attempt to maintain splenic function. Immune protection by these splenic fragments is incomplete at best, because of the loss of the normal splenic circulation. The presence of Howell–Jolly bodies on the peripheral blood smear indicates decreased splenic function, placing the patient at risk for overwhelming postsplenectomy infection (OPSI) [66]. Although Howell–Jolly bodies may be detected by autoanalysers, a manual blood film should be reviewed if there is a clinical question of hyposplenism.

Epidemiology

The incidence of OPSI is impacted by many factors, including underlying
disease, patient age, age at time of splenectomy, time elapsed since splenectomy, pneumococcal vaccination, and antibiotic prophylaxis. Reported incidence rates are highest among patients with underlying thalassemia, intermediate in patients with sickle cell anemia, malignancy, or hematologic disorders, and lowest among patients who undergo splenectomy for trauma.

Encapsulated bacteria are the most common organisms causing OPSI. *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* are the organisms of greatest concern. *S. pneumoniae* is the most frequently isolated pathogen, representing over 50% of cases of OPSI. Other bacterial pathogens include *Salmonella* spp. [60], *Capnocytophaga canimorsus* [67,68], which is associated with dog bites, and *Campylobacter* spp [69]. There has been one reported case each of OPSI as a result of *Mycobacterium tuberculosis* [70] and *Mycoplasma pneumonia* [71].

Asplenic individuals are also at risk for severe infection with the intraerythrocytic pathogens *Babesia microti* and *Babesia bovi*. Both organisms are transmitted by tick bites; *B. microti* is endemic on islands off the northeastern coast of the United States (Long Island, Nantucket Island, Martha’s Vineyard), whereas *B. bovi* is found in Europe. The acute phase of malaria may be more severe in splenectomized individuals, but splenectomy may be protective in the chronic phase. Atypically, severe cases of *Plasmodium vivax* and *Plasmodium ovale* have been reported in splenectomized individuals, and relapse of malaria following splenectomy has occurred [60].

**Diagnosis**

**Clinical Presentation**

OPSI should be considered in any febrile patient with a history or abdominal scar consistent with splenectomy or disease process associated with hyposplenism. The initial symptoms of OPSI are fever, headache, abdominal pain, vomiting, and diarrhea. There may be a nonspecific prodrome characterized by low grade fever and myalgias. If untreated, the disease evolves into fulminant septic shock and death over 2 to 5 days [72]. In advanced cases, acute tubular necrosis, adrenal cortical necrosis, and DIC may occur. A petechial or purpuric rash may be seen. Meningitis or pneumonia occurs in approximately one-half of cases; in the remaining cases, septicemia occurs, which is presumed to arise from colonization of the pharynx.

**Laboratory Features**

Blood cultures yield the causative organism for most cases of OPSI.
Infections of lesser severity also occur and may not be associated with detectable bacteremia. Hematologic findings of DIC (thrombocytopenia, elevated prothrombin time, D-dimer, and fibrin split products), elevated serum creatinine, and blood urea nitrogen are frequently seen. Howell–Jolly bodies are found on a peripheral blood film. During the immediate postsplenectomy period, mild elevation in the platelet and leukocyte counts are physiologic, but a leukocyte count higher than 15,000 cells per μL after the fourth postoperative day suggests that infection is likely the cause [73].

**Differential Diagnosis**

OPSI may be mistaken for uncomplicated sepsis if the history asplenia or hyposplenism are not appreciated. Thrombotic thrombocytopenic purpura may also have a similar presentation, with fever, thrombocytopenia, and acute renal failure.

**Management**

In addition to supportive care, antimicrobial therapy should be initiated promptly. Third-generation cephalosporins are active against *S. pneumoniae, N. meningitidis*, and *H. influenzae* in most locales. Cefotaxime 2 g intravenously every 8 hours or ceftriaxone 1 to 2 g intravenously once daily may be used for uncomplicated cases [74]. If meningitis is suspected, the dose of cefotaxime should be increased to 2 g every 4 to 6 hours, and ceftriaxone should be given in a dose of 2 g twice daily. If pneumococci with high-grade resistance to penicillin and cephalosporins are prevalent in the region, vancomycin should be added until culture and susceptibility data become available. Patients with a severe allergy to penicillins and cephalosporins may be treated with vancomycin given with chloramphenicol or a fluoroquinolone [61]. Expert consultation should be sought in such cases.

**Prevention**

Prevention of OPSI entails ensuring adequate vaccination, prompt evaluation and empiric antimicrobial treatment for febrile episodes, and, possibly, prophylactic antibiotics. Current recommendations include vaccination with the 13-valent pneumococcal conjugate vaccine (PCV13) followed by the 23-valent pneumococcal polysaccharide vaccine (PPSV23) at least 8 weeks later [75]. If possible, the series should be completed 2 weeks or longer prior to splenectomy. If that is impractical, it is recommended that patients be immunized as soon as possible postoperatively. Recent observations that antibody levels are improved if
Vaccination is delayed until 14 days postoperatively [76] must be weighed against the risk that vaccination may be overlooked if it is not carried out prior to hospital discharge. A reasonable compromise may be to immunize the patient at hospital discharge. A second dose of PPSV23 should be administered 5 years later [75]. Meningococcal conjugate vaccine (MenACWY) should be administered to patients who are asplenic or who have splenic dysfunction [39]. In addition, serogroup B meningococcal vaccines have recently been made available and are now recommended for use in patients aged 10 years or older with anatomic or functional aspenia [59]. Owing to the ongoing risk for meningococcal disease in asplenic persons, MenACWY vaccination should be repeated at 3- to 5-year intervals [39,77]. The conjugate H. influenzae vaccine should be administered to asplenic patients according to the standard schedule for all children [78]; unvaccinated persons aged 5 or older should receive one dose [75]. Influenza vaccine should be administered annually owing to the risk of secondary bacterial infection [79].

Lifelong antibiotic prophylaxis is recommended by some authors [78], whereas others question this approach [60]. The data supporting prophylaxis are stronger for the pediatric population than for adults [61]. In the first 2 years following splenectomy of a child, or of a patient with thalassemia or immune deficiency, antibiotic prophylaxis is recommended by most experts. Penicillin remains the drug of choice, despite emergence of resistance among some isolates. Ideally, it should be dosed twice daily, but if adherence is an issue, it may be given once daily. Erythromycin may be substituted for patients who are allergic to penicillin. “Stand-by” antibiotics, to be taken early in the course of a febrile illness, is a strategy favored by all [60,78]. Amoxicillin-clavulanate is a good choice for this indication. Patients must be counseled to seek medical care when they have a suspected infection, and not rely on stand-by antibiotics alone.
In developed countries, malaria is primarily seen among travelers, immigrants, and military personnel, but, in the developing world, it is a major cause of morbidity and mortality. There are between 300 and 660 million cases that occur annually worldwide, resulting in 700,000 to 2.7 million deaths each year [80]. Imported cases have increased throughout the world; in the United States, over 1,600 cases were reported to the National Malaria Surveillance System, a passive reporting system administered by the CDC in 2012 [81]. This represents an overall increasing trend of malaria cases in the United States since the 1970s [81]. In 2003, Plasmodium falciparum was identified as the causative species for 53% of cases; 70% of the cases were acquired in Africa. Virtually, all of the fatal cases of malaria in the United States are caused by P. falciparum. Although the great majority of cases occurred among persons who did not follow a CDC–recommended prophylaxis regimen, it must be noted that approximately 20% of patients with malaria reported taking appropriate chemoprophylaxis. Failure to take a recommended regimen resulted in fatal malaria in seven reported cases since 1992 [82]. There have been small clusters of mosquito-borne malaria transmission within the United States as well as occasional congenital cases and transmission via blood transfusion [83]. This discussion will focus on severe malaria, and its management in critical care settings.

Etiology

Plasmodium is an intracellular parasite that sequentially infects hepatocytes and then erythrocytes, resulting in clinical malaria. Four species cause disease in humans: P. falciparum, P. malariae, P. ovale, and P. vivax. Plasmodium is transmitted to human hosts by its vector, the female Anopheles mosquito.

Pathophysiology
